Glossary

Bridging plants Plants utilized in habitat restorations to provide resources for pollinators during resource-poor time periods.

Ecosystem services A set of resources and processes provided by ecosystems that contribute to human well-being.

Food security The availability and access to sufficient, safe, and nutritious food for a community or individual.

Framework plants Plants utilized in habitat restorations to provide resources necessary for supporting large numbers of pollinator species or individuals.

Phenology Plant and animal life cycle events that are often periodic and usually influenced by seasonal variations in climate.

Pollination The process by which pollen is transferred from anthers to stigma, initiating sexual reproduction and formation of the fertilized fruit or seed.

Pollinator networks A visual display of plant–pollinator interactions, usually based on visitation or pollen-load data.

Pollinator network connectance The proportion of plant–pollinator links observed in a network (links/species).

Pollinator network nestedness Where specialists interact with subsets of species with which generalists also interact, creating a 'nested' structure.

Perhaps one of the most critical yet understudied factors affecting the decline of global pollinator populations and pollination services are alterations in local and regional climatic conditions. In the past few decades, humans have significantly altered climatic conditions due to the emissions of aerosols, and of greenhouse gases, including CO_2, and from land management practices (NRC 2005) consequently impacting wild species distributions and population dynamics across the world (reviewed by IPCC 2001; Parmesan 2007; Parmesan and Yohe 2003). Because most pollinators are completely reliant on plants for food resources, pollinator populations maybe both indirectly affected by changes in the abundance, spatial distribution, and timing of flowering in plant populations, and directly affected by the climate of the regions in which they occur. Thus, the discussion of climate impacts on pollination services requires an analysis of both direct and indirect interactions between climate, plants, pollinators, and the many threats to plant and pollinator populations (**Figure 1**).

In this chapter, we review scientific literature surrounding four key topics: (1) the ecological interactions related to pollination services and vulnerability, (2) the ecosystem services provided by native pollinators and their potential alteration, (3) mitigation possibilities for improved pollination acquisition, and (4) the resulting policy implications (**Figure 1**). Given the large scope of this topic, we focus on insect pollinators, which are one of many pollinator groups

Climate
Pathogens, Habitat loss, invasive species, chemical sprays, nutrient cycling, etc
Plants (native and crop)
Native pollinators
Managed pollinators
Temporal mismatch
Spatial mismatch
1. Ecological interactions
Altered pollination networks / Biodiversity loss
2. Ecosystem service changes
Altered quantity, quality and availability of native/crop seed set
3. Mitigation possibilities
Improved local habitat (size and quality)
Improved regional habitat (size and quality)
Increased use of managed pollinators
4. Policy implications
Design policy that conserves native pollinators and their foraging and nesting resources
Implement practices that extend floral resources at the beginning and end of flowering season
Provide incentives for favorable land-use practices, like biodiverse organic farming, alternatives to paving and tilling, and reduced spraying of chemicals

Figure 1 Framework showing how climate influences plants and pollinators, and thus the availability and quality of ecosystem services. Part 1 of the figure is adapted from Hegland, S. J., A. Nielsen, A. Lazaro, A. L. Bjerknes, and O. Totland, 2009: How does climate warming affect plant-pollinator interactions? Ecol. Lett., 12, 184–195, and the remaining parts indicate the change in ecosystem services and role of management practices and policies on pollination services, respectively. Dashed lines and arrows indicate areas not covered by this review.

(e.g., birds, mammals), but are the most economically important pollinator groups globally (Roubik 1995; Winfree et al. 2011a). Because very little literature is available on the direct impacts of climate on pathogens, chemical sprays, and other threats to pollinators, we only speculate on these topics and advise that greater research is required for an understanding of these factors. Because one of the objectives of this review is to provide ecologically informed management suggestions for improved pollination services, we focus on native pollinators, which have the potential to provide sustained pollination services. Compared to the services provided by a single species of managed pollinator (e.g., the honey bee), species-rich communities of wild pollinators can provide redundancy in terms of pollinator services (Kremen et al. 2004) and thus may provide services that are more stable over time (Garibaldi et al. 2011) and in the face of environmental change. However, we suggest that climate impacts on managed pollinator communities are topics of great importance and require further study. Overall, by summarizing the literature relevant to climate impacts on native pollinators, we provide generalizable and ecologically informed management suggestions for scientists and policy makers across communities and ecoregions.

4.11.1 Ecological Interactions

4.11.1.1 Pollination Services

Ecosystem services are the set of ecosystem functions that contribute to human well-being and include provisioning, supporting, regulating, and cultural services (Daily 1997; Millenium Ecosystem Assessment 2005). Pollination of plants by animals is both a regulating and a supporting ecosystem service. As a regulating service, it is essential for the reproduction of pollinator-dependent plants that supply humans with foods, fiber, forage, biofuels, firewood, timber, and medicine. The contributions of pollination services to human well-being may be direct or indirect. Direct contributions include fruit or seed production of pollinator-dependent food, fiber, biofuel, and forage crops (e.g., alfalfa, apple, blueberry, canola, cherry, cucumber, cotton, longan, macadamia, melon, raspberry, squash, soy, and sunflower). Indirect contributions of animal pollination include the reproduction of tree species valued for timber (e.g., mahogany, White et al. 2002), sown crops in which the vegetative parts are eaten, seed production (e.g., lettuce, broccoli, carrot), vegetatively propagated crops in which animal pollinators are required for breeding only (e.g., potatoes, banana), and pollinator-dependent plants with medicinal properties [e.g., *Catharanthus* spp., which include the famous Madagascar periwinkle (reviewed in Klein et al. 2007; Miyajima 2004)]. As a supporting service, pollination is essential to maintain populations of pollinator-dependent wild plants (Aguilar et al. 2006) that then provide additional ecosystem services, such as erosion control, water filtration, carbon storage, and habitat for biodiversity (discussed in greater detail in the following sections, reviewed in Kremen et al. 2007).

Of these various contributions to human well-being, scientists have to date only rigorously quantified importance of pollination services to food crop production (e.g., effects of animal pollination on fruit and seed yield, and on seed production for crops in which vegetative parts are eaten). These studies have shown that 75% of all crop species depend on animal pollinators to produce fruits or seeds, either partially or completely, supplying 35% of global crop biomass (Klein et al. 2007). Importantly, these crops also supply the majority of certain essential micronutrients in plant-based food, such as dietary lipid (74%), vitamins A (70%), C (98%), E (35–66% of tocopherols) and folate (55%), and minerals calcium (58%) and fluoride (62%) (Eilers et al. 2011). Since some crop production from animal-pollinated crops is due to self or wind pollination, the total amounts of biomass and micronutrients due to yield increases from animal pollination will be less than these numbers, but remain substantial (Eilers et al. 2011; Klein et al. 2007). Worldwide, the pollination services for food crop production, including both those provided by managed bees imported to crop fields and those freely provided by wild bees, were recently valued at €153 billion/year (prices from year 2005), 9.5% of global crop value (Gallai et al. 2009).

Neither the micronutrient nor the economic calculations include the contributions of vegetative crops for which animal pollinators are needed for seed production or breeding. We also lack recent quantitative analyses of the indirect contributions of pollinators to meat and dairy production via forage production (e.g., alfalfa, McGregor 1976), as well as, any calculations of pollinator contributions to fibers, medicinals, botanicals, firewood, timber, and other useful plant species, both cultivated and wild. As 87% of wild plants are pollinator dependent (Ollerton et al. 2011), these contributions are likely to be large.

We can conclude that the contributions of pollinators to human well-being are many and varied. To the extent that wild pollinator species provide these services, then growers do not have to pay beekeepers to supply them, reducing input costs for growers, as well as, food prices for consumers (Chaplin-Kramer et al. 2011; Winfree et al. 2011b). Wild pollinator species still provide sufficient pollination services in certain regions (e.g., Winfree et al. 2007b; Winfree et al. 2008) or in favorable environments within regions (e.g., Garibaldi et al. 2011; Kremen et al. 2002), but in general, with the intensification of agriculture and the loss of natural habitats, both the magnitude and stability of wild pollinator richness, visitation rates, and pollination services have declined in landscapes around the world (Garibaldi et al. 2011). In fact, these declines in pollination services occurred despite no observed declines with intensification in the abundances of the honey bee, *Apis mellifera*, a managed species which growers frequently import to their fields for pollination services.

Declines in the abundance and richness of wild pollinator populations are therefore already having subtle consequences for the human food supply, although these are largely masked by the presence of managed honey bees (Garibaldi et al. 2011). Such effects may intensify as managed honey bees have suffered dramatic declines in some regions (Neumann and Carreck 2010), probably due to synergistic effects of disease, environmental stress, and pesticides (Potts et al. 2010), and wild pollinators are also declining, especially in intensive agricultural landscapes (Garibaldi et al. 2011; Winfree et al. 2009). Declines in wild pollinators will also have large consequences for the reproduction of wild plant populations (Aguilar et al. 2006) that are likely to ramify in their effects on food chains and ecosystem services, potentially affecting both wildlife and humans.

What are the major factors causing wild pollinator declines? Several recent synthetic analyses focusing on bees, the principal pollinators of most crops and many wild plant species, note the loss or degradation of habitat as the principal factor in declining richness and/or abundance (Bommarco et al. 2010; Williams et al. 2010; Winfree et al. 2009). At the landscape scale, meta-analysis showed that pollinator richness and abundance were significantly affected by extreme habitat loss or simplification, but not by moderate habitat loss (54 studies, Winfree et al. 2009); conversely, favorable management practices in farming or grassland landscapes (such as organic farming or set-asides on farmlands or grazing intensity for grasslands) had significant positive effects on abundance and richness of pollinators only in simplified (<20% of non-crop habitats), but not complex landscapes (46 studies, Batary et al. 2011). Guild characteristics affected the response of bees to different habitat disturbance types, as shown in a quantitative synthesis of 19 studies including over 600 bee species; in particular, above-ground nesters and social species were more sensitive to various types of disturbances than below-ground nesters and solitary species (Williams et al. 2010). Social species were negatively affected by pesticide use, but this factor was not significant overall or for other guilds (Williams et al. 2010). Additionally, a few recent studies have shown that pesticide application can have negative impacts on native bee species abundance and richness (Tuell and Isaacs 2010), and declines occur at both local and landscape scales and are more likely to occur after multiple applications (Brittain et al. 2010). However, very little is currently known about the complexities of pesticide impacts on wild pollinators and further research is required to understand the influence of specific pesticide application techniques and chemicals on pollinator life history and behavior in the field.

4.11.1.2 Sensitivity/Vulnerability of Pollination Services

4.11.1.2.1 Temporal Mismatch

Our understanding of the effects of climate on pollination services is weak, in part because determining individual plant and pollinator responses to climate is a vast task, and scaling those responses up to the community level is challenging, given the complexity of such interactions. Pollinator visitation to plants is a community-level phenomenon—merely knowing the species present does not necessarily indicate how they will interact to provide pollination services. In particular, behavioral changes in pollinator foraging may play an important role (e.g., Greenleaf and Kremen 2006) in determining the effects of climate on pollination services. Climate may cause changes in the quality, quantity, and timing of floral rewards in space, and pollinator behavioral responses to those changes are difficult to predict. Furthermore, pollinator behavior is layered on top of changes in pollinator timing and abundance in space. We may begin to piece together potential effects of climate on pollination by considering evidence for each of these pieces separately. To determine the sensitivity and vulnerability of pollination services to climate, we will first review what is known about how plants and pollinators themselves are being affected. (Much of this work has been reviewed previously by Burkle and Alarcon (2011) and Hegland et al. (2009).)

Although the phenologies of some insect pollinators and many plant species have been shown to be affected by warming, few studies have found temporal mismatches in plant–pollinator interactions. Honey bees, bumble bees, and some butterflies are active earlier with warmer temperatures (e.g., Dennis and Sparks 2007; Gordo and Sanz 2006; Sparks et al. 2010) and many plant species are flowering earlier with warmer temperatures, as well (e.g., Amano et al. 2010; Fitter and Fitter 2002; Miller-Rushing and Primack 2008; Sparks et al. 2000). The majority of reported phenological changes for plants and pollinators show advanced activity, yet some show delayed phenology (e.g., Doi et al. 2008; Von Holle et al. 2010), illustrating the need for detailed, and possibly species specific, investigations of different systems before generalizations can be made. In addition, variability in early-season phenologies of plants, and to a lesser degree, butterflies, is increasing (Menzel et al. 2006). When flowering phenologies were experimentally advanced and plants were placed in an unmanipulated community (e.g., the phenologies of pollinators were allowed to unfold naturally), few mismatches were observed (Rafferty and Ives 2011). By resampling and comparing plant–pollinator phenologies and interactions with historical phenologies and interactions, it is possible to test the degree to which interactions are being disrupted by phenological changes. In a comparison spanning 120 years, few mismatches in plant–pollinator interactions directly attributable to phenological change were found (Burkle et al. in prep). These empirical investigations, though limited in number, suggest that temporal mismatches may not play as large a role in decoupling plant–pollinator interactions as previously indicated by models (Hegland et al. 2009; Memmott et al. 2007).

Despite the lack of evidence for widespread temporal mismatches, given the current degree of changes in climatic conditions in some regions, there are likely some cases in which mismatches have led to declines or extirpations of plant and/or pollinator populations. Demographic consequences of such temporal mismatches, however, are not well understood. Thomson (2010) showed strong direct effects of frost events and snowmelt patterns on the reproduction of glacier lilies. Temporal mismatches of glacier lily flowering and the activity of their pollinators may also limit seed set, though this has not been investigated explicitly. Burkle et al. (in prep) have observed the extirpation of half of the bee species historically present in mid-western US forests, though the cause of this bee decline, involving many specialist bees, may not be solely due to temporal mismatches (see below). Effects of climate on pollinator nesting habits and reproduction are largely unknown and have been identified as an important gap in our understanding (Burkle et al. 2011). Miller-Rushing et al. (2010) outlined a way to better understand the demographic effects of phenological mismatches, including key questions and approaches using experiments, models, and long-term data.

4.11.1.2.2 Spatial Mismatch

In addition to temporal mismatches influencing pollination services due to phenological changes in plant and pollinator activity, spatial mismatches may also be as, or more, important. Spatial mismatches between plants and pollinators may occur due to range shifts resulting from climate changes, or due to indirect climate change effects such as habitat destruction and fragmentation. For example, under different climate scenarios, it is possible that humans may use land differently, by altering existing urbanization, development, and/or crop planting patterns, and thus potentially destroying and fragmenting existing habitat. Second, climate can determine the distribution of many plant species, and thus, climate changes can result in spatial shifts in plant populations. Much of the empirical support for range shifts has been performed along elevational gradients in the alpine, where the upward movement of species with warming is relatively straightforward to detect. Plant distributions along elevational gradients can change rapidly with climate, and have been documented as shifting upward in elevation an average of 22 m per decade in the southwestern United States (Kelly and Goulden 2008) and 29 m per decade in western Europe (Lenoir et al. 2008; Walther et al. 2005, 2002). Other studies focused specifically on flowering forbs and their range shifts find similar changes in elevation (Crimmins et al. 2009). In a cross-study comparison, Parmesan and Yohe (2003) found many species, including alpine herbs, to be shifting poleward at an average rate of 6.1 km per decade. In some systems, involving narrowly distributed endemic plants, range shifts may not be possible and declines in species richness have been observed (Damschen et al. 2010). At the other end of the spectrum, some plant species, such as invaders, may adapt and evolve to occupy new environmental conditions associated with climate change, expanding into novel ranges (Gallagher et al. 2010). However, there is also evidence for lack of plant response to recent warming in the alpine, with clones of long-lived plants remaining in the same locations over thousands of years (Bahn and Korner 2003; Steinger et al. 1996). Sherrer and Korner (2010) argue that high microclimatic variation in the alpine would allow plants to ‘escape’ larger scale changes in climatic conditions without moving more than a few meters. Determining which plant species would shift their ranges due to warming and the direction and magnitude of their responses remains challenging.

Few studies have documented range shifts in pollinator species, primarily because knowledge of historic and current distributions are lacking. There are initiatives to map historic pollinator distributions based on museum specimens for comparison to current ranges (Koch in prep). In a few studies, butterfly range shifts have been documented to be moving poleward due to climate changes (Bryant et al. 1997; Kerr 2001; Parmesan and Yohe 2003). Changes in pollinator species distributions are more easily attributed to habitat loss or fragmentation directly (Cane 2001), though the ultimate causes of habitat change may be related to climate shifts and associated changes in human land use. At a local scale of kilometers, loss of historically occurring plant–pollinator interactions can be due to spatial uncoupling in which plants become separated from their pollinating partners in isolated forest fragments (Burkle et al. in prep).

4.11.1.2.3 Alteration of Pollinator Networks

A relatively new method for understanding plant and pollinator interactions at the community level is via the construction of interaction networks (Memmott 1999; Memmott et al. 2004; reviewed in Vazquez et al. 2009). In these networks, single lines connecting plants and pollinators indicate the existence of interactions between two species, making it easier to visualize and analyze changes in these interactions. Examined as a whole, the pollinator network can also convey critical information regarding the structure and function of community-level interactions (reviewed in Burkle and Alarcon 2011; Vazquez et al. 2009). Pollinator network analysis has generally shown that, within sites, there is substantial interannual variation in what pollinators interact with what plants, but despite this variation, pollination events still take place, potentially indicating resilience to environmental change. Interestingly, despite natural variation in who interacts with whom, structural properties of community plant–pollinator networks remain fairly constant over time (reviewed in Burkle and Alarcon 2011). For this reason, it is possible to use network metrics, like **nestedness** and **connectance** to indicate, over and above this natural variation, the health and stability of interactions and potential directional change over time due to anthropogenic environmental changes. Highly nested networks are fairly robust to environmental change (Bascompte et al. 2003); thus declines in the nestedness of a network over time can serve as a barometer, indicating loss of functional resilience in plant–pollinator interactions.

Pollination networks can be utilized to understand community-level impacts of climate change via two main approaches: (1) evaluation of networks after simulated biodiversity loss or phenological mismatch and (2) comparison of networks after actual habitat restoration. We discuss both in the sections below, respectively.

4.11.1.2.4 Simulated Biodiversity Loss or Phenological Mismatch

Simulation studies use existing plant–pollinator networks to simulate the effects of environmental change, for example, they help us to understand what happens when we delete species or advance the phenologies of species, as might be predicted by climate warming. For the most part, these simulation studies have found that pollination networks are more robust to the removal of random species than to the selective removal of highly linked species (Kaiser-Bunbury et al. 2010; Memmott et al. 2004). Many studies have found that the removal of the most-linked pollinator species results in a relatively linear decline of plant species, explained by the nested interaction network topology and a redundancy in pollinator links per plant (e.g., Memmott et al. 2004). In another simulation study, Devoto and colleagues (2007) removed species from the network that they predicted would exhibit spatial range shifts due to climate-change induced increased precipitation, and found that removal of these species had fairly minimal impacts on the plant–pollinator network. In another simulation study by Kaiser-Bunbury et al. (2010), the authors allowed species in the network to switch to those that they have known potential to interact with, with the interesting finding that networks could be stabilized following species loss if remaining species could indeed 'rewire' to form new interactions. While results from these simulation studies suggest that pollinator networks may be more robust to species loss and range shift than other ecological networks (e.g., Dunne et al. 2002), it is important to keep in mind that plants and animals may be differentially impacted by biodiversity loss, given that pollinators represent higher trophic levels, which are inherently more sensitive to habitat disturbance (e.g., Holt et al. 1999; Kruess and Tscharntke 1994). Because pollinators are dependent on plants for food, it is not surprising that removal of the strongest interacting species in the network can have the strongest negative impact on simulated animal extinction rates (e.g., Kaiser-Bunbury et al. 2010).

Just a few pollinator network studies have examined the impact of climate on pollinator networks by modeling plant and pollinator phenology (Memmott et al. 2007, 2010). In these studies, Memmott and colleagues use existing predictions of temperature changes (e.g., IPCC 2001) to calculate potential phenological shifts in plant and pollinator emergence and senescence, if those predictions are accurate. In their 2007 study, Memmott and colleagues examined simulated networks where the onset of flowering and flight activity of all plants and pollinators would be advanced by 1, 2, and 3 weeks. Across all three scenarios, they found that 17–50% of all pollinator species, especially those with smaller and more specialized diet breadths, faced reduced floral resources and potential extinction. Similar to the findings of other network studies, the predicted impacts on pollinators were much greater than for plants, though plants still experienced a 50% reduction in pollination activity, likely leading to reduced reproduction and eventual population decline (Memmott et al. 2007). In a following study, Memmott and colleagues asked specifically how the sowing of wildflowers changes the impact of simulated climate on the pollinator network. Their experimental planting and simulated climate-impacted network showed that by sowing plant species that bloomed at the beginning and end of the flowering season, the overall period of nectar resource availability could be extended for pollinators. However, it should be noted that these simulation studies did not allow for behavioral flexibility, which might allow for new interactions to develop between plants and pollinators within the system.

Another potential interaction between climate and pollination systems may be the introduction of non-native species into the pollination network (Memmott and Waser 2002; reviewed in Schweiger et al. 2010), which may occur if non-native species become invasive under those environmental change conditions (reviewed in Dukes and Mooney 1999; Walther et al. 2009). Depending on whether non-native plants interact negatively or positively with native plants, their invasion could stabilize or destabilize pollinator networks. Examination of a plant and pollinator network in central United States has shown that non-native plants are far more common than non-native pollinators (Memmott and Waser 2002). In this study, non-native plants interacted with significantly fewer pollinator species than native plants, but were still relatively well connected in the network. Likewise, in another simulation study specifically examining the removal of non-native species, the pollination network's structural integrity was diminished by non-native species loss, due to the high levels of connectivity between alien and native species within the pollinator network (Valdovinos et al. 2009). Thus, if non-native plant species increase overall floral resource availability and duration, they may positively impact pollinator populations in the short term. However, the long-term effects of non-native plant species on pollinator populations are not well known. Invasion, which leads to plant species declines and losses in resource heterogeneity, may negatively impact forager biodiversity, as seen in other systems (e.g., Macarthur and Macarthur 1961; Shmida and Wilson 1985; Tylianakis et al. 2008). Overall, these studies suggest that non-native species play varying roles in pollinator networks, depending on their ability to provide foraging resources and their impact on the native plant community.

4.11.1.2.5 Network Comparison Post Habitat-Alteration

Comparing interaction networks before and after an event (habitat destruction or restoration) can tell us more about the maintenance of pollination services than typical biodiversity studies can. Unfortunately, though empirical research on the spatial and temporal variation of plant–pollinator networks is badly needed, the lack of historic data and the intensive sampling effort required to identify multiple empirically gathered networks has limited research in this area (Hegland et al. 2009). Only a few empirical network studies have specifically examined how habitat alteration impacts network architecture. Forup and Memmott (2005) compared pollinator networks for old intact hay meadows and restored hay meadows (planted with native plants post-agriculture), and found no significant difference between the two in terms of plant or insect species richness or abundance, but did find that old meadows had a slightly higher proportion of potential links between plants and pollinators. In a second study, Forup et al. (2008) examined ancient and restored heathlands and found that, while the plant and pollinator communities were similar, the interaction networks were significantly less complex, in terms of connectance values, in the restored heathlands. These results suggest that even in 'restored' human-altered landscapes supporting similar levels of species diversity, the complexity of plant–pollinator interactions may not be easily recreated, and this may ultimately limit the long-term persistence of plant and pollinator communities. In communities with high degrees of network complexity, such as the species-rich plant and pollinator communities of the tropics (Bawa et al. 1985), network recovery post human-alteration may be less likely.

Most remaining studies have examined plant–pollinator interactions over time within the same sites, and these have largely focused on intra- and inter-annual variations in network dynamics (reviewed in Burkle and Alarcon 2011). Studies comparing networks within a single year have often found substantial species turnover in composition, emphasizing the need to consider plant–pollinator networks for shorter and more biologically relevant time periods (Basilio et al. 2006; Jordano et al. 2003; Medan et al. 2006; Petanidou et al. 2008). One study that examined plant and pollinator interactions on a daily basis, also found pronounced species turnover, and found that the most connected species, and thus perhaps the most resilient species, were those with the longest flowering–foraging periods (Olesen et al. 2008). Studies that have examined variation in pollinator networks across multiple years have also found a large degree of turnover in species composition, but have surprisingly found that the number of plant and pollinator species, connectance, degree of nestedness, and modularity were conserved over the years (Alarcon et al. 2008; Burkle and Irwin 2009; reviewed in Burkle and Alarcon 2011; Dupont et al. 2009; Petanidou et al. 2008). Overall, these studies indicate that plant–pollinator systems are dynamic, but that pollinators are flexible in resource use, potentially making networks more resilient to climate change. Furthermore, they indicate that high levels of connectance and nestedness allow for functional redundancies in the network, and greater potential resilience to climate change-induced biodiversity loss. However, research on pollinator networks over multiple years is sorely needed (reviewed in Burkle and Alarcon 2011), specifically research which examines how habitat alteration and environmental change impacts complex and spatially explicit pollinator network architectures (reviewed in Gonzalez et al. 2011). These future studies will greatly improve our understanding of environmental change impacts on pollinator community dynamics.

4.11.2 Ecosystem Service Changes

As mentioned earlier in the chapter, plants and pollinators provide a number of critical ecosystem services. Throughout this chapter, we have discussed research indicating that alterations in local and regional climate can disrupt plant and pollinator phenology, potentially leading to population and community alteration. In our discussion of pollinator networks, we have further shown that simulated alteration of plant and pollinator phenology can lead to marked changes in community-level interactions. The consequences of these population-level and community-level alterations on ecosystem services could be various, and include potential changes in the quantity, quality, spatial availability, and temporal availability of ecosystem services. Unfortunately, research that directly examines the impact of the various dimensions of local climate change on pollination service acquisition is rare to nonexistent. In the following paragraphs, we discuss how potential outcomes of warming or warming and drying scenarios, specifically reduction in the abundance and diversity of pollinators, may impact ecosystem services provided by wild plants and native pollinators.

4.11.2.1 Wild Plant Pollination

The impact of pollination disruption on wild plant communities and the ecosystem services they provide is potentially wide-ranging, but largely understudied (Tylianakis et al. 2008). Though more than 75% of wild plant species are dependent on insect pollination for reproduction (Ollerton et al. 2011), the impacts of this dependency on community or population level ecosystem services are not clear. Most existing studies have focused on single-species analyses of wild plant reproductive success across varying habitat treatments (e.g., Fenster and

Dudash 2001; Jules and Rathcke 1999). A recent meta-analysis of these studies has found that self-incompatible pollinator-dependent plant species exhibited greater declines in fragmented habitats than self-compatible plant species (Aguilar et al. 2006), and cross studies, the effects of fragmentation on pollinators were highly correlated with the effects on plant reproduction. Both of these findings suggest that pollination limitation could be a key driver for wild plant population decline. Of the wild plant species studied, 62–73% show pollination limitation (Ashman et al. 2004; Burd 1994), and though the long-term consequences of pollen limitation on population growth are uncertain (Hegland and Totland 2008), simultaneous declines in native plant and pollinator populations suggest a link between these two patterns (Biesmeijer et al. 2006). Thus, wild plants may face declines if their pollinators exhibit climate-induced spatial or temporal change, or general population decay.

Biodiversity loss in wild plant communities can have devastating effects on ecosystem services because wild plants are critical for ecosystem processes in both natural and human-altered landscapes. Aside from providing humans with food, medicines, fuel, and construction materials, wild plants also support important processes in agricultural, rural, and urban landscapes, such as pest-predation (reviewed in Chaplin-Kramer et al. 2011), nitrogen fixation (e.g., Hooper and Vitousek 1997), erosion control (e.g., Philpott et al. 2008), water filtration and storage (e.g., Lin and Richards 2007), and carbon sequestration (reviewed in Hooper et al. 2005). Lastly, wild plants provide habitat needed for the migration of important seed dispersers and serve as plant propagule reservoirs for the recolonization of disturbed habitats (e.g., Jha and Dick 2008). Thus, wild plants are critical for the function and regenerative capacity of natural and human-altered landscapes, and their decline would undoubtedly reduce the depth and range of ecosystem services they currently provide.

4.11.2.2 Crop Plant Pollination

As discussed in the introduction of the chapter, animal pollination is important for crop production and contributes to the stability of food prices, food security, food diversity, and human nutrition (Steffan-Dewenter et al. 2005). An estimated 15–30% of the American diet depends on insect pollination (reviewed in Losey and Vaughan 2006) and globally, the cultivation of pollinator-dependent crops is growing (Aizen et al. 2008). Thus the loss of pollinators, without strategic market response, could translate into a production deficit of an estimated −40% for fruits and −16% for vegetables (Gallai et al. 2009). These studies all suggest that climate-induced pollinator declines or disruptions to crop pollination could result in the alteration or reduction of food quantity, quality, diversity, availability, and nutritional content, potentially compromising global food security.

4.11.3 Mitigation Possibilities

A number of options exist for improving conditions for pollinators and buffering disruption of pollination interactions and general biodiversity loss. Unfortunately, very little research on pollinator restoration has been conducted specifically in the context of climate. In the following paragraphs, we present mitigation strategies that have been developed with respect to other types of environmental change, as they serve as key starting points for climate-specific restoration strategies. Though many of the practices for pollination restoration are similar, restoration projects can vary in their specific objectives and thus may have different concepts of restoration success (Menz et al. 2011). In particular, we focus on local and regional habitat mitigation strategies that are aimed at increasing the abundance and diversity of native pollinators, but also briefly discuss the challenges and opportunities for better developing pollinator restoration practices in the context of climate. Generally, the best insurance for protecting pollination services in the face of any alteration in local and regional climate involves maintaining or restoring high abundances and diversities of wild pollinators, their food plants, and their nesting resources throughout their current and predicted geographical ranges.

4.11.3.1 Local Habitat Restoration

Research on local habitat restoration strategies is the most well-studied area of pollinator conservation and includes a wide range of on-site practices, such as the sowing flowering strips and installation of hedgerows. Pollinators are dependent on both flowering and nesting resources (Kremen et al. 2007; Potts et al. 2005; Williams et al. 2010; Winfree 2010). Thus, it is essential to consider pollinator nesting and floral resource needs while deciding on the location, size, configuration, and longevity of the restoration. When considering the selection of plants to include in the local restoration, it is also critical to consider nectar and pollen needs of the target pollinator community across their foraging periods (e.g., Dixon 2009; Williams et al. 2010). Some studies suggest the strategic planting of **'framework'** and **'bridging' plants**, which respectively, provide resources necessary for supporting large pollinator numbers and provide resources during resource poor time periods (Dixon 2009). Bridging plants may become even more important, if there is a mid-summer decline in floral resource availability associated with warmer conditions (Aldridge et al. 2011). Furthermore, it is important to consider the facilitative and competitive interactions between the plants within the restoration in order to select a mix that optimizes resource availability for pollinators, as well as, reproductive capacity for the plants themselves (reviewed in Menz et al. 2011).

For the restoration location, field margins are the most commonly utilized areas within agricultural areas (Carvell et al. 2004; Meek et al. 2002; Pywell et al. 2006), because they are usually not planted with crop plants and are often long and linear, easing the process of sowing, planting, and weeding. Within crop fields, field margins and adjacent lands, flowering strips, especially those that include non-legume forbs (e.g., Pywell et al. 2006), are a low cost method to provide pollinators with floral resources. These flowering strips have been shown to increase the abundance and diversity of native bees and butterflies for at least a single season, often more (e.g., Potts et al. 2009; Pywell et al. 2006). Resowing of these strips can provide extended resources and also help reduce the occurrence of weeds (Potts et al. 2009). If a longer term restoration is preferred, hedgerows that include woody perennial plants can potentially provide both nesting and floral resources (Menz et al. 2011).

4.11.3.2 Regional Habitat Restoration

Regional habitat restoration strategies for pollinator conservation include the preservation of unmanaged natural habitat and modifications of existing practices on human-managed lands. A number of studies have shown that the preservation of natural habitat within agricultural areas can lead to higher pollinator abundances, richness, and pollination services for adjacent crops (reviewed in Kremen et al. 2007). Furthermore, the presence of remnant habitats can be critical for the colonization of recently restored habitats (Forup and Memmott 2005; Forup et al. 2008). Human-altered regional habitat can also be used to support pollinator populations, if managed appropriately. Minimizing grazing and cutting of grasslands can increase regional floral resource availability (Duffey et al. 1974; Kruess and scharntke 2002) and insect nest site availability (Morris 2000; Woodcock et al. 2007). Pasture that is infrequently grazed can provide bee populations with important floral and nesting resources (e.g., Morandin et al. 2007), and the reduction of fertilizer application, in conjunction with reduced grazing, has been shown to provide improved habitat for a number of butterfly species (e.g., Erhardt 1985).

Whether natural habitat is preserved or human-managed landscapes are modified for pollinator conservation, it is essential to consider the role of habitat restoration in supporting essential regional pollinator dispersal and migration processes, which may vary depending on pollinator community (reviewed in Menz et al. 2011; Powell and Powell 1987; Ricketts 2001). A number of spatial simulation models of pollinator restoration have shown that the best habitat restoration design for pollinator persistence and pollination service was strongly influenced by the foraging behavior of the target pollinator species (Brosi et al. 2008; Keitt 2009). Thus, restoration should keep in mind the dispersal capacities of target pollinator species (reviewed in Menz et al. 2011). For example, for highly mobile species, the restoration processes can consider creating a 'stepping stone' habitat (e.g., Ottewell et al. 2009), whereas dispersal limited species may need more contiguous linear corridors of high-quality habitat (Tewksbury et al. 2002) to facilitate movement through inhospitable matrices. In fact, within agricultural settings, plant populations connected by corridors (Townsend and Levey 2005; Van Geert et al. 2010) or highly biodiverse matrices (Jha and Dick 2010) have been shown to participate in extensive pollen transfer. Thus, habitat restoration that facilitates pollinator movement has the potential to support improved pollination services across natural and human-altered landscapes, particularly in light of current and plausible future changes in local and regional weather patterns and climate.

4.11.3.3 Pollination Restoration and Climate

The habitat-restoration strategies discussed in this chapter provide only indirect options for buffering global climate change; however, the act of increasing pollinator abundance and species richness in a community, at the least, increases the probability that a community or population can persist in altered conditions. Increased population densities and gene flow levels usually lead to populations with greater adaptive genetic diversity (sensu Conner and Hartl 2004). These genetically diverse populations are more likely to be comprised of individuals genetically more suited to altered habitat conditions. Furthermore, there is substantial research illustrating that many ecosystem processes are a function of biodiversity levels (e.g., Balvanera et al. 2006; Cardinale et al. 2006; Naeem 2009) and that ecosystem process change is often less marked when biodiversity levels are high, due to the potential functional redundancy among species (Montoya and Raffaelli 2010) and response diversity (the differing responses of different species to the same environmental change) (Winfree and Kremen 2009). Thus by maintaining high population-level genetic diversity and community-level species diversity, restorations can provide potential safeguards against future ecosystem alterations from climate and other environmental stressors.

Furthermore, it is possible to take the mitigation strategies discussed above and adapt them to the specific situations predicted in global climate model change scenarios. One potential result based on these scenarios is a temporal or spatial shift in species flowering or foraging, which would be likely given that species exhibit varying responses to climate (Parmesan 2007). As discussed in the previous section, one pollinator network study suggests that one way to make pollinator restoration habitats more resilient to future climate conditions is to extend the flowering season of existing restoration areas (Memmott et al. 2010). While this study provides insight into how potential phenological changes could be incorporated into existing restoration plans, there are a vast number of restoration strategies that require further research in the context of climate change. Specifically, future work is needed to examine the role of nesting resources and flowering species density in altered climate conditions.

4.11.4 Conclusions and Policy and Management Implications

While conservation biologists are often focused on taking measures to adapt existing management strategies to whatever climate plausibly could occur in the future or to create new strategies that are more resilient, the goal to develop policies that minimize all human climate forcing needs to be a high priority.

The next line of defense is to ensure that conservation management strategies, both existing and in planning, are designed with climate effects in mind. Many of the recommended strategies for making protected areas more resilient to climate (Heller and Zavaleta 2009) are also those long recommended as best practices for conservation, such as ensuring connectivity between reserves, encompassing latitudinal and elevational gradients within reserves or reserve networks, creating buffer zones around reserves, and ensuring that land-use practices in the matrix are favorable to biodiversity. Given the enormous existing challenges of implementing conservation action successfully (Knight et al. 2008), the concordance between recommended conservation measures for adapting to climate, including plausible changes in local and regional climatic conditions, and other environmental threats is indeed a welcome relief. This concordance also signals how important it is, in the face of climate risks, to enact a full suite of multi-scale conservation measures on the ground to deal with the multiple, synergistic effects of interacting drivers of local and global extinction (Heller and Zavaleta 2009).

Conservation of pollinator biodiversity falls within this general set of recommendations. Thus, rather than repeating this ground, we focus here on the maintenance and conservation of pollination function, rather than pollinators per se, and recommend five key focal points for policy and management, at local and regional scales.

LOCAL:

- Maintaining pollination function in an area requires maintaining a locally diverse set of pollinator species. Diverse groups of pollinators provide enhanced pollination function, through complementarity and other mechanisms (Hoehn et al. 2008; Klein et al. 2009), and are more likely to withstand multiple, potentially synergistic, threats, through response diversity (Winfree and Kremen 2009). Actions that maintain or restore the diversity of pollinators locally are therefore critically important.
- Maintaining the diversity and abundance of floral resources is a key factor in maintaining the local diversity of pollinators (Potts et al. 2003). Therefore, it is important to enact policies and implement actions that provide floral resources in working lands, including agricultural, urban, pastoral, and plantation landscapes. Such landscapes can support high bee diversity under proper management (e.g., Batary et al. 2011; Cane et al. 2006; Holzschuh et al. 2008; Kremen et al. 2002; Winfree et al. 2007a).
- In restoring plant communities to support pollinators, it is important to ensure that a phenological sequence of plants is established that provide bloom throughout the pollinators' flight season (Menz et al. 2011). For added resilience to climate, specific attention should be paid to enhancing resources at the beginning and end of the flight season (Memmott et al. 2010).

REGIONAL

- Maintenance of the regional species pool is equally important. Extensive research has shown that the landscape scale is an extremely important influence on pollinator abundance and diversity (Garibaldi et al. 2011; Ricketts et al. 2008), and that local scale amelioration of habitat tends to augment pollinator diversity and abundance only in the most simplified landscapes (Batary et al. 2011). Therefore, maintaining sufficient natural habitats at the regional scale is critical for supporting healthy pollinator communities and services (Chaplin-Kramer et al. 2011; Kremen et al. 2002).
- Favorable local scale management practices, such as organic farming practices can have landscape level effects that add to the local effects of such management practices (Gabriel et al. 2010; Holzschuh et al. 2008).

Given the critical role of wild pollinators in maintaining a nutritional human food supply (Eilers et al. 2011; Garibaldi et al. 2011; Klein et al. 2007; McGregor 1976), and the recent and widespread losses of our principal managed pollinator, *Apis mellifera* (Neumann and Carreck 2010), policies and conservation management plans should accord special attention to maintaining the diversity and resilience of pollinator communities, especially in the face of global climate change.

4.12.1 Introduction

Forests are the largest plant community association on earth (FAO 2010) and provide a wide array of services. They occupy 52% of the earth's land surface (**Figure 1**). They are the largest terrestrial primary producers and sequester the largest amount of atmospheric carbon dioxide (CO_2) on land. In the mountainous parts of the world, forests provide protection against landslides and avalanches. Through their interactions with the atmospheric system, forests regulate environmental conditions, preventing seasonal water shortages or dampening the extent of flooding. They provide a physical barrier that protects soils from erosion and reduces sediment loads in water courses. Forests provide a structure that sustains habitat for countless organisms and, as such, contain a large proportion of global biodiversity (S.o.t.C.o.B. 2010). Forests are also a primary source of fuel in many parts of the world and even provide food. Many of the services provided by forests have high societal value but have little direct monetary value associated with them. Other services have well-established economic values: Forests provide fiber for the global wood products and paper industry. In other parts of the world, forests support a large

Figure 1 Forested lands of the world as derived from the moderate resolution imaging spectroradiometer (FAO - Global Forest Resources Assessment 2010).

recreational industry. These ecosystem services are essential to sustaining healthy human societies.

The quality and level of ecosystem services are regulated by functional processes that occur in forests. Studies of ecosystem function have greatly contributed to the understanding of sustainable production of forage, fiber, fuel, and provision of water via forests. Without ecosystem functions intact, ecosystem services are greatly reduced. Improved knowledge of ecosystem function and the maintenance of productivity are key factors in determining adaptation measures and mitigation options, as well as in helping to achieve long-term sustainability and stability in the many parts of the world. Even in the anthropogenic progressive buildup of global carbon dioxide (CO_2), the signal of forests is visible. The oscillation in the Keeling curve, a graph that plots the ongoing change in CO_2 concentration since 1958 (Figure 2), is caused by forests. More CO_2 is removed from the atmosphere during the summer in the northern hemisphere, where there is a higher concentration of forests and, consequently, more photosynthesis during the summer months, than in the southern hemisphere summer (Figure 2). This has led many scientists and policy makers to speculate that forest ecosystems can be managed to ameliorate problems related to global warming.

Through ecological services provided by forests, every human is either locally or globally affected by the level of forest productivity in some way. Ecosystem services are often provided in direct proportion to forest productivity. Stability in levels of forest productivity is a good representation of the state of the ecological mechanisms that maintain the structure and services supplied by forests. Forest productivity, driven by these ecological mechanisms, is mediated by conditions at molecular scales, by regional and local environmental conditions, and by disturbance and forest management activity. The strong link between forest productivity and ecosystem services makes forest productivity level a powerful surrogate for the interaction between global environmental changes and ecosystem services.

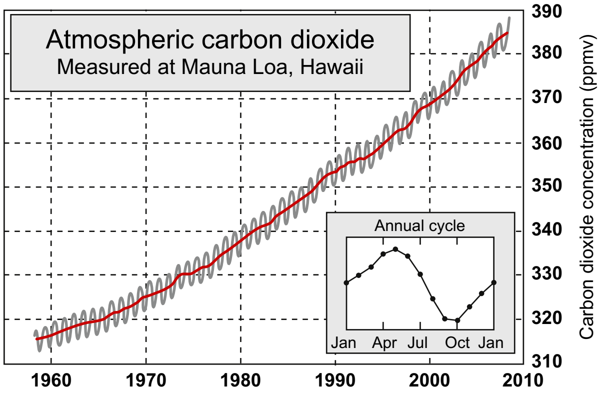

Figure 2 Atmospheric CO_2 levels as measured at the Mauna Loa observatory. This curve is known as the Keeling curve, in honor of Dr Charles David Keeling, the researcher who initiated these measurements.

Forest productivity can be measured in relation to any of the above ecosystem services provided by forests. Forest productivity is most often quantified in terms of carbon fluxes. Productivity begins at the cellular level via photosynthesis, the process by which plants convert carbon into organic compounds. The level of photosynthesis is referred to as gross primary production (GPP) and is a quantity of carbon taken from the atmosphere via photosynthesis. Net primary productivity (NPP) is this amount of photosynthate (carbon) minus the amount consumed by the maintenance of biological processes ($R_{\text{maintenance}}$ – maintenance respiration).

$$\text{NPP} = \text{GPP} - R_{\text{maintenance}}$$

The Intergovernmental Panel on Climate Change (IPCC) (IPCC 2003) defines NPP as the rate of carbon accumulation in plants after losses from plant respiration and other metabolic processes (necessary to maintain the plant's living systems) are taken into account. Net ecosystem productivity (NEP) takes into account heterotrophic respiration such as decomposition of dead organic matter, and thus can be measured from the changes in carbon stocks in vegetation and soil or by integrating fluxes of CO_2 in and out of the system (IPCC 2003; Goulden et al. 1996). Productivity can also be assessed by the level of greenness of forests [e.g., normalized difference vegetation index (NDVI) – (White et al. 2005)], the amount of wood production (e.g., m^3 ha^{-1} (Milner et al. 1996)), or by levels of biomass (e.g., Kindermann et al. 2008).

The environment in which plants are growing is changing. Assessments of how these changes affect forest productivity are crucial to our understanding of how the services provided by forests may also be changing and how adaptation strategies can be developed. In this chapter, we (1) provide a general understanding of the drivers of forest productivity; (2) synthesize documented responses of forest productivity to environmental changes, and based on this state of knowledge; (3) evaluate the risks that come with these and future changes; and (4) present a final synthesis of adaptation and mitigation options.

4.12.1.1 Basic Factors Affecting Forest Productivity

Photosynthesis and respiration are fundamental processes that are the basis for forest productivity and central to ecosystem structure and function. Both respiration and photosynthesis are affected by water availability and temperature, but respiration produces CO_2 while photosynthesis requires CO_2. Photosynthesis is also affected by the amount of incident light. Productivity, as measured by NPP, is the balance between photosynthesis and respiration. Atmospheric CO_2 levels are rarely a limiting factor to productivity. Rather, the basic drivers, temperature, radiation, and water, interact to impose complex and varying limitations on vegetation productivity in different parts of the world (Running et al. 2004; Nemani et al. 2003; Churkina and Running 1998; Boisvenue and Running 2006). Figure 3 depicts the distribution of the limiting abiotic factors to primary production in terms of water, sunlight, and temperature on a global scale. Very few forest types in Figure 3 appear as solid colors, thus expressing variability in the dominance of limiting factors within a given year. For example, the productivity of a forest at northern latitudes is constrained by radiation for some portion of the northern hemisphere winter months due to short day lengths. In late winter, spring or fall, the same forest may have enough light, but low temperature becomes the limiting factor to productivity. Finally, water stress may limit productivity in the warm months of summer. Worldwide, forests have tended to occupy more temperature and radiation-limited environments (Churkina and Running 1998). Currently, less than 7% of forests are in strongly water-limited systems on a global scale.

Temperature (heat) controls the rate of plant metabolism, which in turn determines the amount of photosynthesis and respiration that take place. Most biological metabolic activity takes place within the range of 0–50 °C (Hopkins and Hüner 2004). There is little metabolic plant activity above or below this range. The optimal temperatures for productivity coincide with 15–25 °C, which is the optimal range of photosynthesis

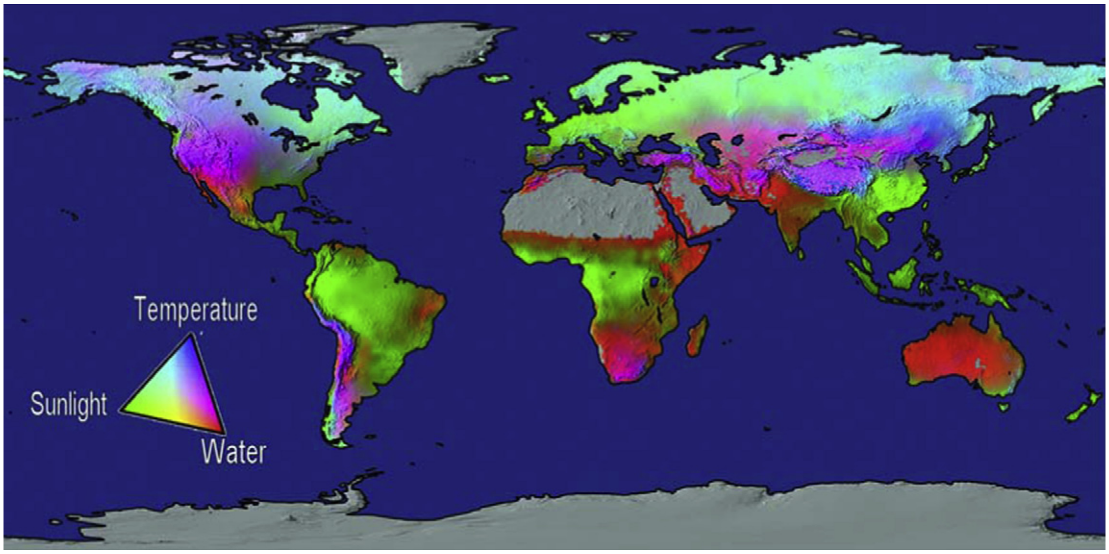

Figure 3 Potential limits to vegetation net primary production based on the fundamental physiological limits of vapor pressure deficit, water balance, and temperature (Boisvenue and Running 2006).

(Hopkins and Hüner 2004). Whereas, temperatures between 44 °C and 52 °C can be lethal (Schulze et al. 2002). Photosynthesis depends on radiation and increases with increasing levels of radiation up to a saturation point. Water is a principal requirement for photosynthesis and is the main chemical component of most plant cells. In dry regions, there is a linear increase in NPP with increased water availability (Loik et al. 2004).

4.12.1.2 Tree and Site Effects

Changes in the basic drivers of forest productivity are first and foremost in determining levels of productivity. If light or water levels are too low or if temperatures are outside the range for metabolic activity, there can be no photosynthesis. Where these basic conditions allow for photosynthesis, the level of forest productivity is further refined by forest type, site, and landscape characteristics. Following the basic drivers, species composition, age and stand structure, site nutrient status, physiological adaptation of the trees, disturbance, and land-use change are the first variables to affect productivity.

4.12.1.2.1 Age and Structure

In addition to stand type and composition, the age and physical stand structure also affect productivity (Battaglia 2001). As forest age increases, productivity generally increases to an asymptote and declines thereafter. However, exceptions to this decline can be found. For example, some old growth forests on the west coast of North America seem to maintain high NPP. High turnover may limit net production of biomass on highly productive sites (Keeling and Phillips 2007). Field measurements demonstrate that biomass, which in many cases is an appropriate surrogate for NPP, rapidly increases in early stand development and tends to stabilize after a certain number of years. The number of years to reach this stability varies by species and forest type, e.g., 200 years in Oregon forests (Van Tuyl et al. 2005). Measurements of carbon storage and fluxes at different developmental stages also show the change in carbon fluxes with increasing age [e.g., ponderosa pine (*Pinus ponderosa* subsp. ponderosa Douglas) forest (Almeida et al. 2004)].

4.12.1.2.2 Nutrients

Nutrients available to support carbon fixation and productivity depend on many intricately related factors. Field data clearly establish a positive relationship between optimum nutritional status, optimum available water, and productivity (Albaugh et al. 2004). The underlying geological formation or geomorphological deposit may contribute to site productivity, but the presence of essential elements does not necessarily make them available for forest growth. For example, nitrogen (N) is one of the most abundant elements on earth. Paradoxically however, N deficiency is one of the most common nutritional problems affecting plants worldwide. N is an important component of many structural, genetic, and metabolic compounds in plant cells and a major component of chlorophyll, the molecule responsible for photosynthesis. Microbial communities, the presence of biological N fixers, external N inputs, turnover dynamics, and levels of other nutrients such as sulfur and phosphorus [see (Braun et al. 2010)] are only some of the interacting factors that determine the level of available nutrients (including N) for forest productivity. Forest soils and site productivity are affected by changes in site water balance and temperatures since they affect soil organic matter decomposition rates (Kirschbaum 2004; Barrett 2002; Moore et al. 1999; Trofymow et al. 2002). Decomposition rates regulate mineralized nutrients available to plants, which affects photosynthetic carbon gain in nutrient-limited systems (Kirschbaum 2004).

4.12.1.2.3 Physiological Interactions

Physiological responses to changes in environmental conditions are highly dependent on the limiting factors of a particular site to forest growth, which, may vary seasonally for the same location. Some studies have found exponential decreases in productivity with decreased water availability (Webb et al. 1983); others confirm strong correlations between precipitation and productivity (Fang et al. 2001; Knapp and Smith 2001). However, the relationship between productivity and precipitation is not always obvious at finer temporal or spatial scales, e.g., the correlation between interannual variability of both precipitation and productivity levels is not always strong (Brando et al. 2010). This is due to the multiple role of water in metabolic plant activity and in ecosystem level processes such as decomposition and mineralization.

Increasing temperature, which has been shown to have a positive effect on productivity (e.g., Toledo et al. 2011), also increases vapor pressure deficit of the air, thereby increasing transpiration rates. This results in adverse effects on drier sites in summer, unless stomata close in response to other changes, such as an increase in CO_2. Increases in night temperatures, if they exceed increases in daytime temperature, can also reduce stomatal conductance (Kirschbaum 2004). Some tree species seem to be able to alter certain traits in response to environmental conditions. One important trait that exhibits some plasticity is water use efficiency (WUE) (Bergh et al. 2003; Gagen et al. 2011). Physiological traits, such as number of stomata, WUE, and foliage light-use efficiency are thought to vary across ecosystem types, and even within a single tree canopy, but how these traits vary across species and time scales is still under debate (Nichol et al. 2002; Guo and Trotter 2004; Lagergren et al. 2005). In a subsequent section, we give an overview of the observed and modeled physiological responses to changing conditions, including changes in traits.

4.12.1.2.4 Disturbance and Land-Use Changes

Land use and land-use change have more direct effects on productivity. Changing forest types, such as planting a new species following a disturbance or forest removal for urbanization both change productivity levels. The United Nations has established a program aimed at minimizing impacts of land-use change on forests (REDD – Reducing Emissions from Deforestation and Forest Degradation, see http://www.un-redd.org/). Disturbances, especially large-scale and intense disturbances, inherently change the productivity of forests (Metsaranta et al. 2010; Bergeron et al. 2010; Pfeifer et al. 2011) because some or all of the photosynthetic material (the carbon fixing material) is removed during disturbances while other material can be left to decompose (which consumes carbon). Most disturbances are either driven by or indirectly linked to climatic conditions (Bergeron et al. 2010; McKenzie et al.

2004; Collins et al. 2006; Dymond et al. 2010). Disturbances have even been shown to delimitate forest type ranges (Bergeron et al. 2004) or be driven by them (McIntire and Fortin 2006). Historical disturbances (i.e., the sequence of disturbances that have effected a specific site) leave a legacy that affects forest dynamics and by interim, productivity (McIntire et al. 2005).

In summary, beyond the basic productivity drivers (temperature, radiation, and water), forest productivity is affected by tree and site characteristics. These include forest composition, age, structure, site nutrient status, and tree physiological response as well as external inputs or larger-scale changes such as atmospheric deposition, land-use change, and past and present disturbances.

4.12.1.3 Larger Scale Effects

There are less direct controls on forest productivity than temperature, light, and water, and than the tree or site-level characteristics. The level of productivity is further refined by forest phenology, biodiversity, forest stand and landscape dynamics, and by feedbacks between changes occurring in forests and the global environment.

4.12.1.3.1 Forest Phenology

Forest phenology refers to the timing of natural events through the seasons. These events include flushing or budburst, flowering, fruiting, and autumn leaf-fall. Phenology is partly driven by amounts of light, water, and temperature, but also by tree genetics. It dictates when it is possible for plants to photosynthesize. Growing season length determines yearly NPP in temperate and boreal forests (Kimball et al. 2004). Data and modeling demonstrate that spring and autumn climate thresholds impact forest productivity and that responses vary by site and species (e.g., Bergh et al. 2003; Desai 2010). Warming that would decrease winter chilling could result in delayed bud burst and adversely affect flowering and seed germination for some species (Chmura et al. 2011), thereby reducing productivity.

4.12.1.3.2 Biodiversity

Biodiversity, as measured by species richness, has also been shown to affect productivity (Paquette and Messier 2011) but it seems to be less of a factor on more stable and productive environments than in the more stressful environments (e.g., temperate versus boreal forests). Mechanisms such as niche complementarity, where the number of species occupying a site can be increased when species have specialized niches, increase biodiversity and consequently increase productivity through stand structure (Paquette and Messier 2011). Species composition can alter the level of productivity as different species under constant environmental conditions display inherently different levels of productivity. Plantations exploit this differentiation between species (e.g., Mallik et al. 2008).

4.12.1.3.3 Forest Dynamics

Ecological succession drives large-scale changes in ecosystem composition over time. The collective response, however, is still the behavior of individuals; individual trees have to produce seed, disperse these seeds, die, etc., for stand dynamics and ecological succession to occur. Thus, all components of individual tree life cycle (tree seed production, seed dispersal, and tree mortality) indirectly determine forest productivity. Seed production and dispersal are the first step in landscape-level forest dynamics, post-disturbance dynamics, and eventually, in species composition. The level of seed production and how these seeds are dispersed are thereby an indirect component of forest productivity (Nathan et al. 2011). In a similar way, tree mortality has direct effects on the dynamics of woody biomass, species composition, stand structure, wood production, and consequently, on forest response to climate.

Even if the individual tree is the unit of change, landscape, regional, continental, and global assessments are still required. Large-scale assessment is an indicator of ecosystem health. The maintenance of a functioning ecosystem is necessary for the maintenance of ecosystem services – trees alone, although they are the unit of change, do not form an ecosystem with societal services but their collectivity does. Cross-scale analyses (such as looking at productivity at the leaf, tree, and system level) quantify the productivity for the system as a whole and contribute to a better understanding of how processes are linked through scale, how these processes can be maintained and they may permit us to see different processes that act at different scales. At the ecosystem scale, losses due to disturbances are relatively infrequent and difficult to quantify. At the biome scale, however, disturbances such as fires and forest harvest can be considered processes because they occur on a regular basis in one area or another of the biome (Georgii and Yoshiki 2002) and, as such, become quantifiable and perhaps even predictable.

4.12.1.3.4 Forest Bioclimatic Feedbacks

Forests are affected by their environment but they also affect their environment. High temperatures can increase transpiration through canopy conductance returning water particles to the atmosphere, which in turn affects the water content of the atmosphere contributing to modifications to atmospheric processes. Other changes, such as an increase in CO_2, can cause stomata to close and by consequence limit transpiration. Changes in physiological traits happen at small scales but their collective change can lead to global-level responses. These feedback loops are influenced by the physiological modification that occurs when climatic conditions change. These cycles are termed physiological feedbacks. One of these feedbacks is based on the notion that providing plants with higher levels of CO_2 will enhance productivity (CO_2 fertilization effect) and contributing to lowering the anthropogenic increase in atmospheric CO_2 by fixing more CO_2 in plant material. CO_2 levels will certainly affect the productivity of some forests, but experimental and modeling studies reveal huge variations in this physiological forcing.

Another feedback comes from a more physical process where the reflectance contribution of forests to the global energy balance can be changed by the level of energy reflected back to the atmosphere. Albedo is the reflective power of a surface. Forests are generally not highly reflective; only between 5 and 15% of incident radiation on forest canopies is reflected back into the atmosphere. A change in forest cover may sufficiently change the radiative forcing of the surface to enhance or counter the increase in atmospheric temperature. The images in **Figure 4** show the change in land surface

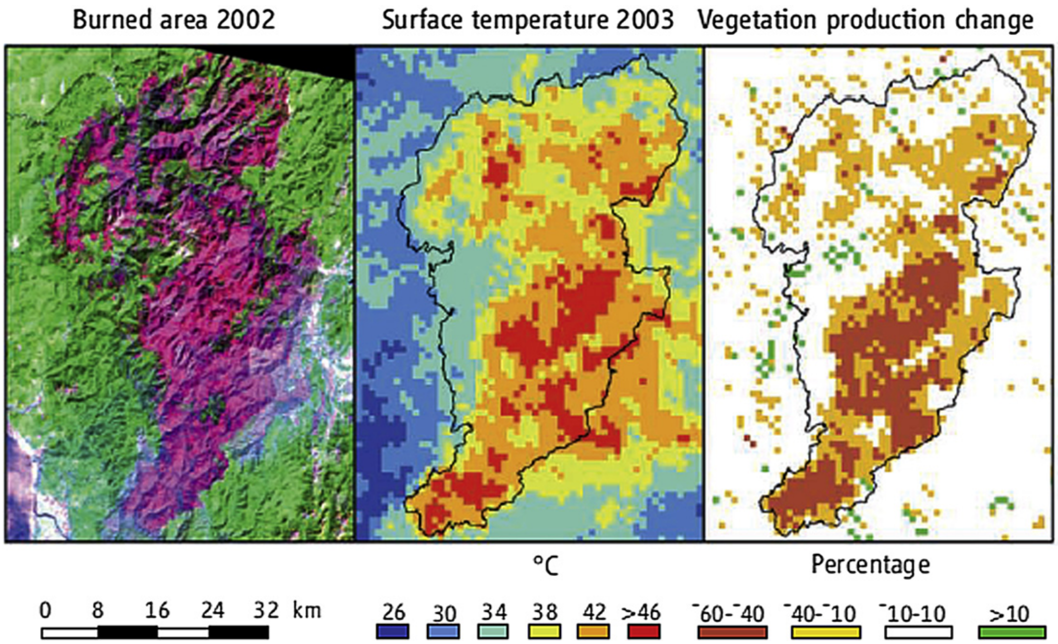

Figure 4 Impact of fire disturbance on land surface energy and carbon balances (Running, 2008). In the summer of 2002, the Biscuit Fire in Oregon burned 2000 km^2 of temperate evergreen forests (left). A moderate resolution imaging spectroradiometer (MODIS) satellite image taken on 28 July 2003 (middle) shows land surface radiometric temperatures of 46–50 °C in the area burned the summer before, whereas temperatures in the adjacent unburned forests range from 27 to 32 °C. Annual vegetation production measured from MODIS (4) (right) was 20–60% lower in the burned area in 2003–04 than before the wildfire.

temperature in the year following a fire in Oregon, on the west coast of the United States. This change in temperature is due to the change in reflective power of the surface and is an important feedback to the atmosphere, changing the energy balance from what it was prior to the fire. Similar changes in reflectance levels may occur if a closed boreal forest becomes more open: There is a process that occurs in the boreal forest called paludification that does exactly this. A more open boreal forest shows much more ground-snow in winter than a closed boreal forest, changing the energy balance of the atmospheric system. There is increasing information available on the effects that forests exert on the global system (e.g., chapter 10B of 64). Unfortunately, most feedback processes are neither well understood nor constrained.

In summary, intricate internal linkages within the forest ecosystem between the forest and the atmosphere bring to light the effects of larger scale processes on forest productivity. Forest phenology, patterns of carbon allocation by individual trees or species to seed production, and the species' mechanism of seed dispersal, as well as its mortality traits, all have indirect effects on productivity levels through forest composition and dynamics. It is also important to assess productivity at different scales of forest ecosystems and to account for the effects that forests have on their local and global environments.

4.12.2 Environmental Changes and Productivity Responses

In many regions, changes in weather patterns and atmospheric composition in the last 50 years have significantly altered the environmental conditions in which forests grow (Jones and Mann 2004). There is evidence that forests have already responded to these changes (Boisvenue and Running 2006; Allen et al. 2010), and changes in environmental conditions are predicted to intensify in the coming decades (IPCC 2007). The IPCC Fourth Assessment Report summarizes many research efforts on climate projections and their potential effects on forests. Forests may have to adapt not only to changes in climate variables, but also to a possible increased variability with, therefore, a greater risk of extreme weather events such as prolonged drought, storms, and floods.

As revealed in the previous section, there is considerable variability in productivity controls across forests systems. For example, changes in rainfall patterns would likely have large corresponding effects on forest productivity in regions where productivity is water-limited. Similar statements can be made about radiation and temperature changes. There is so much variation in space and time in projected environmental conditions and in intrinsic conditions of forest systems, that an example of almost any response can potentially be found. In the following section, we explicitly distinguish between actual responses and projected response. We discuss scale and data issues in the next section (Evaluating Risks) and we consistently attempt to keep the observation scale in perspective when describing responses.

High-latitude regions of North America and Eurasia have been identified as key indicators of the effects of changing environmental conditions because productivity in these regions is limited by the combination of climatically controlled factors, and is affected by compositional atmospheric changes, but is relatively free of other driving forces of productivity changes such as urbanization, political change, and other land-use changes. Much research has also concentrated on these regions and we therefore often default to these forests as examples with empirical data. Process-based models open the way to useful predictions of the future productivity rate of forests and provide a means of assessing the probable effects of variations in climate, disturbance, and physiological forcings on forest productivity. Models are a means of synthesizing known processes or established quantitative relationships that enable the exploration of possible outcomes and enable us to link experimental results with cross-scale monitoring data sources. We therefore include results from modeling research in the following discussions of forest responses to environmental changes.

4.12.2.1 CO_2

The global atmospheric CO_2 concentration is now over 393 ppm, well above preindustrial levels of 278 ppm. There has been much speculation and many experimental and modeling studies that attempt to quantify a generalized effect of increased CO_2 levels on forest productivity. Important research advancements have come from Free Air CO_2 Enrichment sites (FACE). FACE sites use methods and infrastructure to experimentally enrich the atmosphere enveloping portions of a terrestrial ecosystem with controlled amounts of CO_2 without using chambers or walls, effectively removing the constraining 'pot effect' that plagues much of the experimental research. Initial results on the effect of CO_2 enrichment seemed to support an increase in productivity (Nowak et al. 2004; Norby et al. 2005; DeLucia et al. 2005; Körner 2004). The effect of CO_2, however, is currently thought to be site specific (Nowak et al. 2004), constrained by available N and nutrient levels (Beedlow et al. 2004; Lloyd 1999; Norby et al. 2010), with CO_2 levels still contributing to higher productivity on specific sites for specific species (Cole et al. 2010), but likely over a limited time-span. A globally consistent increase in productivity due to a CO_2-fertilization effect is not likely.

Physiological modeling results (Kirschbaum et al. 1998) also show that the effect of increasing CO_2 on forest growth can substantially differ between forests due to interactions with a range of factors that affect nutrient supply.

4.12.2.2 Nitrogen

An important contribution to site nutrient status and hence to productivity, may be the increase in atmospheric N deposition. Atmospheric deposition originating from anthropogenic sources has now become the dominant source of N and varies from ~ 0 to $60\,\mathrm{kg\,ha^{-1}\,year^{-1}}$. Atmospheric N deposition is likely to enhance growth for many forests, where N is considered to be the most common limiting nutrient (Breymeyer et al. 1997; LeBauer and Treseder 2008; Tateno and Chapin Iii 1997). The intrinsic nutrient status of a site will determine the response to additional N deposition (much like that suggested for the response to CO_2). There is a substantial geographic variation in current and projected N deposition levels. At very high deposition levels, N can have toxic effects on plants with 'high levels' being relative to the initial nutrient status of the site. In forests, varying levels of N can change the nutrient balance enough to cause a species shift and increase acidity, especially when N deposition is combined with sulfur (S) deposition that may lead to saturation and elevate base leaching from the soil in some forests, effectively decreasing the nutrient status of the site. High levels of N deposition have been shown to increase sensitivity to stress and disturbances. There are also concerns of the continued effects of N deposition on plant biodiversity: Increases in N inputs may favor specific species and eliminate others. Globally, N and carbon (C) cycles strongly interact and can geographically mediate ecosystem response to N within certain biome types. This strong link means that the impacts of N will have additional repercussions on previously described feedbacks and exchanges between the forest and the atmosphere within the climate system.

4.12.2.3 Other Pollutants

The photochemical oxidant ozone (O_3) and pollutants such as sulfur dioxide (SO_2) have been shown to damage plants (Kita et al. 2000; Potter et al. 2002; Ashmore 2005). However, the combined effects of pollutants, CO_2 levels, temperature, and changes in precipitation are not mechanistically well understood (Kirschbaum 2004; Ashmore 2005; DeLucia et al. 2000, 1994). In localized studies, higher levels of O_3 and other pollutants were associated with insect-related disturbances (Jones et al. 2004), suggesting an increase in pollutant-related stress increases the likelihood of occurrence of other stressors. O_3 was also found to interact with frost (Oksanen et al. 2005), increasing the negative effects of frost on pigment loss and stomatal conductance. Integrating O_3 with CO_2, temperature, and precipitation changes within models, results in varying productivity predictions (Hanson et al. 2005). Single factor studies may help us understand mechanisms but they may not be useful in determining the magnitude of long-term ecosystem responses, since combined factors may cancel or compound each other (we discuss this concept in depth in a subsequent section). There is no doubt that the increase in atmospheric O_3 will modify the response of forest to elevated CO_2, temperature, precipitation, and radiation. But few multifactor experiments currently exist and our modeling efforts are bound by our understanding of the interactions.

4.12.2.4 Growth, Temperature, and Precipitation

Air temperature can have different impacts on photosynthesis and respiration (and consequently on productivity) and responses to temperature vary across sites. Also, how these temperature changes affect forests depends on site conditions at the onset and during each event; increases in growing season length may increase photosynthesis in the spring but also increase respiration at the end of the growing season on the same site. Temperature also has a direct effect on decomposition rates; for example, when water is not limiting, decomposition rates increase (at least initially) with increases in temperature. Increased decomposition rates could result in more readily mineralized nutrients available to plants, which would likely increase photosynthetic carbon gain in nutrient-limited systems. The combined effect of CO_2, N, and temperature increases points to increases in productivity. Indeed, initial reports have shown increases over the latter part of the twentieth century in Europe, North America, and in many forests of the world. Increases in above-ground productivity, a commonly targeted variable in many studies, are not necessarily accompanied by an increase in biomass or below-ground carbon accumulation. Field studies show some forests loosing soil carbon while still exhibiting an increase in photosynthesis and in above-ground biomass accumulation.

Temperature increases can lead to increases in metabolic activity, but there is a threshold beyond which high temperatures with no additional water input lead to drought events. Recently, global reductions in productivity due to drought have been reported with varying responses between the northern and the southern hemispheres, where forests in the northern hemisphere show an increase in the last decade and those in the southern hemisphere showed decreases. To result in a productivity increase, temperature increases must be accompanied by a minimum amount of site water.

4.12.2.5 Physiological Interactions

Physiological responses to climatic stresses are relatively well-understood at the organ or whole-plant scale but not at the stand or landscape scale. The rising atmospheric CO_2 levels during the past century have resulted in increases in WUE for some forests. This, however, has not necessarily prevented growth decline due to warming-induced stress. The modification by trees of their WUE may help with drought-tolerance, but apparently extreme events such as summer droughts do not cause an increase in WUE, at least in the short term. Even though physiological responses are not well understood at coarser spatial scales, natural trait variation can still cause large differences in forest productivity. The magnitudes of these differences may approach those arising as a result of changes to site nutrient status and disturbance frequency. In certain regions of the world, physiological responses dominate: In northern and western Europe, the increasing atmospheric CO_2 level and warmer temperatures are expected to result in positive effects on forest productivity, at least in the short to medium term. In eastern and southern Europe, the negative effects of more frequent drought and increased disturbances are likely to outweigh the positive effect of CO_2 or warmer temperatures. In other systems, like the boreal and even some German forests, productivity is more affected by disturbances as opposed to physiological changes due to environmental changes.

Generally, positive responses of conifers to temperature and CO_2 seem to be reported more frequently, possibly because they benefit from a longer growing season. However, declines in productivity during summer water stress also seem more frequently reported for conifers. Radial growth on the best growing white spruce in Alaska seems to have been disproportional affected by increasing temperature. Drought also increases vulnerability to additional stressors or disturbance and may completely change forest dynamics and hence the structure and productivity, which seems to be the case for the Alaskan white spruce. The key is in the identification of the driving forces for a given site and the initial conditions of that site and its history; for example, is the site vulnerable to drought? Do the species on-site have the capacity for adaptation? Will disturbance dominate? Which ecophysiological or phenological trait responds to environmental changes is strongly correlated with species, other traits, geography, and climate? For a specific species, bud phenology, petiole length, and leaf N may be able to adapt to changing conditions, while the traits related to water use may not change; for another species, WUE may be the most responsive trait. A species' distribution since the last glacial maximum may be a good indicator of a species' ability to adapt with wide-ranging species being more likely to exhibit more plasticity in their traits (Bergh et al. 2003; Chmura et al. 2011; Schumacher and Bugmann 2006; Lindner et al. 2010; Falster et al. 2011; Carnicer et al. 2011; Köhl et al. 2010; Keller et al. 2011; Kang et al. 2006).

4.12.2.6 Structure

The increased productivity in forests of the eastern United States in the last 50 years was at least partially driven by age structure; many forests in this region colonized abandoned fields, resulting in forested landscapes with many young stands, stands that are in the steepest and most productive part of their growth curve. The relative effect of structure versus climate (temperature and water combination), nutrient status, or disturbances on productivity was once again site dependent. In Siberian pine forests, age exerted the most control over productivity, followed by site nutrient status, and effects of damage caused by low-grade reoccurring fires (Van Tuyl et al. 2005; Bergh et al. 2003; Wirth et al. 2002; Kardol et al. 2010; Chapin III McGuire et al. 2010; McGuire et al. 2010; Chertov et al. 2009).

4.12.2.7 Insect and Pathogen Disturbances

Modeling results continue to support an increase in productivity due to the combined effect of CO_2, N, and temperature where water is not limited. However, larger scale processes such as disturbance would result in decreases in productivity swamping any response to CO_2, N, temperature, or any possible management intervention. Insects or pathogen disturbances can greatly alter productivity even if they do not completely kill the forest. Forest conditions are certainly a key variable driving these disturbances: Drought stress can increase the occurrence of insect disturbances and pathogen occurrence, but changes to insect and pathogen populations are also occurring and they will affect forest productivity. Pathogens and insects may benefit from facilitated travel associated with a highly mobile human population and better survival conditions due to changes in temperature and precipitation. Even life-cycle changes in native species, such as the mountain pine beetle in the western part of North America, are having dramatic effects on forests (Figure 5). This small native beetle has effectively killed most pine forests in interior British Columbia, Canada, which is an affected area larger than many European countries (Pfeifer et al. 2011; Dymond et al. 2010; Kurz et al. 2008; Régnière et al. 2010).

4.12.2.8 Fires

Dry conditions are conducive to the occurrence of fires. There are numerous reports that fire frequency has recently increased in the western United States and Canada, across the North American boreal forests, and many parts of Europe. Annual levels of burned area have complex relationships with large-scale climatic patterns such as the Pacific Decadal Oscillation,

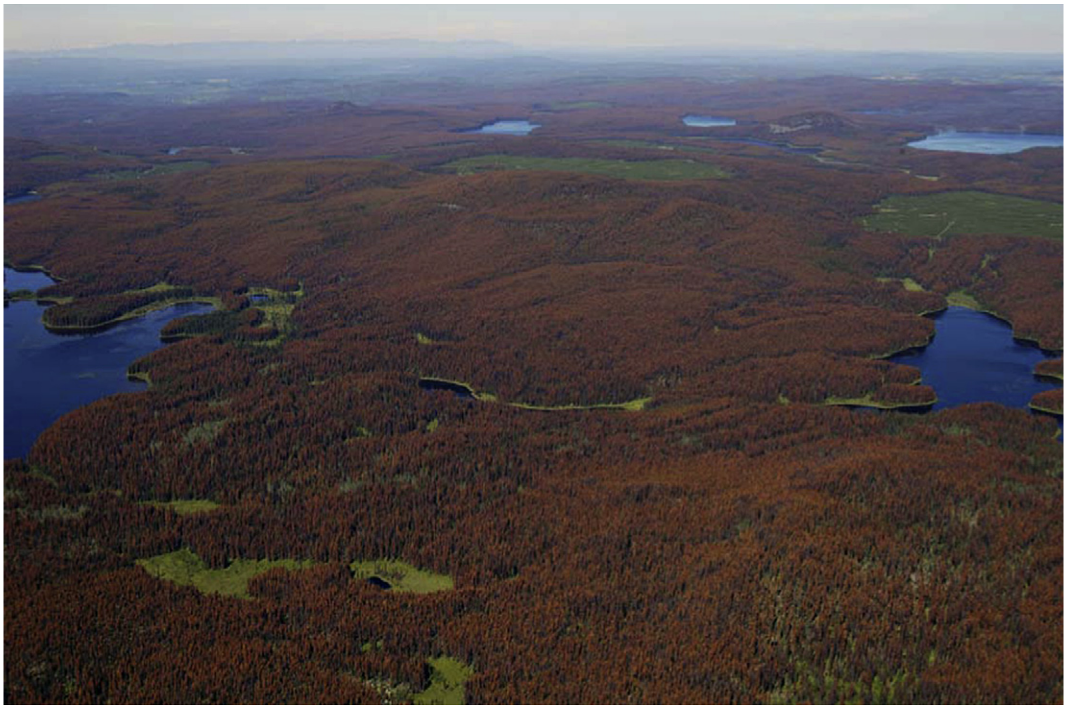

Figure 5 Arial photography of the mountain pine beetle outbreak in central British Columbia, Canada. (Photo credit: Kevin Buxton, Ministry of Forests, BC, Canada.)

the El Nino Southern Oscillation, and the North Atlantic Oscillation. Higher spring and summer temperatures and earlier snowmelt were identified as the main factors extending the wildfire season and increasing the intensity of wildfires in the western United States. These changes are certainly related to larger scale climatic patterns. However, the importance of local and seasonal temperatures and site conditions also suggest that the response of forest fires would be regionally individualistic under the large-scale influence of these weather patterns.

Fire occurrence is also related to other factors such as physiographic factors and human activity. Fire disturbances completely modify site productivity and often drive landscape-level productivity. In forests of the Swiss Alps, fire and physiological responses dominate productivity levels in these forests. Forest fires affect atmospheric conditions by sending a pulse of CO_2 and other gases back into the atmosphere, effectively modifying atmospheric composition. Fires can also drastically change the albedo of the earth's surface, even in the case of less severe fires where clearing of the understory can occur and expose more winter snow for a higher reflectance. Both factors – gaseous pulses and albedo – are feedbacks that can have profound effects on the global energy budget (Metsaranta et al. 2010; Bergeron et al. 2010; McKenzie et al. 2004; Collins et al. 2006; Schumacher and Bugmann 2006; Westerling et al. 2006; van Bellen et al. 2010; Girardin and Mudelsee 2008; Hély et al. 2010; Running 2006; Senici et al. 2010; Macias Fauria and Johnson 2008; Li et al. 2000; Randerson et al. 2006).

4.12.2.9 Mortality

In addition to mortality due to fire, insects, and pathogens, there is currently an increasing number of reports of drought-related mortality events (Allen et al. 2010; Carnicer et al. 2011; Williams et al. 2010; Bigler et al. 2006; Ganey and Vojta 2011; Galiano et al. 2010). Alaskan white spruce is currently experiencing a mortality episode that is thought to be initiated by drought (Soja et al. 2007). There are also reports of large-scale mortality events in Siberian and Canadian boreal forests (Soja et al. 2007), in Scots Pine forests in Switzerland (Bigler et al. 2006), and the Pyrenees (Galiano et al. 2010). Mortality events in forests of the southwestern United States are now well known (Ganey and Vojta 2011). Drought exerts a strong influence on tropical forest metabolism, carbon stocks, and ultimately, the flux of carbon into the atmosphere. Allen et al.'s (Allen et al. 2010) discussion provides a thorough global overview of drought-related whole-stand mortality events. Drought conditions may arise not only from prolonged periods with no or little precipitation, but when precipitation events occur in intense bursts (Lindner et al. 2010; Carnicer et al. 2011; Lines et al. 2010; Williams et al. 2010; van der Molen et al. 2011; Soja et al. 2007; Shiau and Modarres 2009; Misson et al. 2011, 2010; Bigler et al. 2006; Ganey and Vojta 2011; Galiano et al. 2010).

Geographical variation in mortality is substantial and correlated with several environmental factors. Variation in mortality rates is the product of differences in species composition combined with constantly changing mortality–environment correlations within species. The actual response to drought (the extreme response being death) may depend on seasonal timing and perhaps even on the sex of specific trees. Single-season drought events do not necessarily result in mortality, but productivity usually decreases nonetheless. There are fewer reports of decreasing productivity with drought or of partial mortality events, but this may be because detecting small-scale mortality events (e.g., $<30\%$ of a stand) or a decrease in productivity is much more difficult than whole-stand mortality events. Defoliation trends have been reported to be paralleled by significant increases in tree mortality rates in drier areas that are related to tree density and temperature effects. Under the combined effects of drought and defoliators, these forest tree species actually responded by altering their crown leaf structures with increased percentages of defoliation in the drier parts of their distributions.

4.12.2.10 Species Shifts

Fire regimes have been identified as the dominant process in defining boundaries of certain forest types (e.g., boreal mixedwoods and coniferous forests). In some regions, landscape composition perfectly follows the boundaries of past fire events. Biogeographical modeling suggests that species distribution would shift along with changing environmental conditions. Increasing levels of mortality due to drought, fires, insects, and pathogens would certainly contribute to this shift. Biome shifts are reported in Alaska (Soja et al. 2007; Beck et al. 2011), where the boreal forest seems to be expanding into the tundra, and drought-induced productivity declines in interior white spruce stands are shifting the species composition toward a broad-leaved forest (Soja et al. 2007). Shifts are also reported in the boreal forests of Siberia and western Canada (Soja et al. 2007). No northward movement is apparent in the Canadian eastern boreal forest (Payette et al. 2008), which is much wetter than its western counterpart. Drought-induced dieback of Scots pine in the Pyrenees is being accompanied by oak regeneration (Galiano et al. 2010), indicting a species shift; the temperate-boreal ecotone in Canada has reportedly been moving northward (Leithead et al. 2010); there are reports from the Central Alps of a shift toward more drought-tolerant species (Moser et al. 2010). There are also reported shifts in tropical forests, with modeling research suggesting some regions of humid tropical forest contraction, but also some areas of expansion (Zelazowski et al. 2011). Species competition in response to drought is strongly related to the survival strategies of each species (Lines et al. 2010; van der Molen et al. 2011; Zelazowski et al. 2011).

Reported and modeled responses of forest productivity changes along with changing environmental conditions seem to agree that increased levels of ambient CO_2 can increase productivity, albeit over the short term and only for specific sites and species. N is identified as an essential component to this CO_2 response. However, similar to temperature (high temperatures leading to droughts), high N levels can become detrimental to productivity levels. Drought events lower productivity and increase the probability of other stressors or disturbances on forested sites. Reports generally agree that the single or combined effect of drought and other stressors could create more mortality events than in the past. To date, some forests show a predominately physiological response to environmental changes, while the response of other forests is dominated by disturbances. In the next section, we attempt to use acquired observations and knowledge to evaluate the risks to forest productivity that are brought on by environmental change.

4.12.3 Evaluating Risks to Forest Productivity

4.12.3.1 Uncertainty

Before evaluating the risks to forest productivity from current and projected environmental changes, it is important to assess the information that is currently available and on which an evaluation should be based. We start this section by providing a critical assessment of the data and mechanisms that the responses section is based on. We then identify known knowledge gaps that affect the accuracy of interpreting responses, diagnose the limitations of our current synthesis abilities, and look at the potentially compounding effects of the multiple factors affecting productivity. Based on the state of knowledge, we provide an overview of the identifiable risks that environmental changes pose to forest productivity.

4.12.3.1.1 Data, Experiments, and Models

The present understanding of the mechanisms that result in forest productivity come from three main sources: observational data, experimental data, and modeled responses. None of these information sources is perfect. Observational data are limited by sample size, length of observation (time), and spatial scale. Experimental data, resulting from a manipulation of affecting factors, are limited by the number of factors that is possible to change while maintaining an acceptable level of statistical power. Models are often limited by our computational capability and when they are not, they are limited by the extent of the knowledge that can be integrated into model design. All are limited by our ability to analyze, interpret, and understand the system and by research funding.

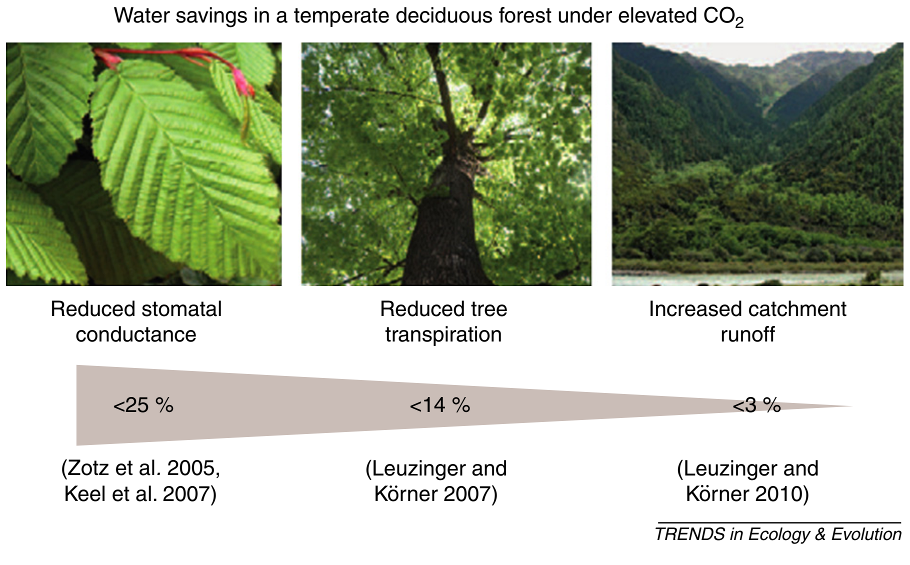
Productivity estimates can come from a variety of data sources. There is often contention on data interpretation with claims of over- or underprediction due to the type or the scale of data used in the analysis, or the analysis itself. Forestry-based data have been claimed to overestimate productivity in temperate and boreal forests (Lloyd 1999), but deciphering the effect of data source among the effects of CO_2, N, temperature, water availability, structure, disturbance, or disturbance history is difficult even with advanced analysis methods. For forest productivity estimates, flux-tower data may be the closest measurement to the actual productivity that is currently available. Flux towers measure the exchanges (mostly of CO_2 and water, but of other gases as well) between the atmosphere and the biosphere. A network of these towers has been established in forest systems around the world. The wealth of information that has come from these sites has contributed to measurable advancement in the understanding of productivity and the links between forest productivity, the atmosphere, and global cycles.

Forest biomass is often equated to productivity. This seems logical given that leaves contain the photosynthetic apparatus and are also an important component of above-ground biomass. However, while this relationship between biomass and productivity is valid for certain sites, it also varies. Processes such as high turnover rates may limit biomass production on highly productive sites (Keeling and Phillips 2007). Some field measurements have revealed biomass to be poorly related to carbon flux and to partitioning of photosynthetically derived carbon (Litton et al. 2007). Field measurements of turnover times also suggest that root production and turnover in forests may have much more site-dependent variability than current generalized estimates suggest (Matamala et al. 2003). These few observations remind us that despite an increasing understanding of carbon allocation in forests, careful attention needs to be paid to how productivity is estimated or inferred, and that the conditions and site for which these estimates were made must be considered before conclusions can be drawn.

Experimental manipulations, both in labs and in the field, are extremely important in understanding the processes that lead to forest productivity. Most of the mechanistic understanding of productivity such as photosynthesis and conductance comes from experiments. However, experiments have their limitations. When attempting to decipher the effect of global change drivers, very few experiments test more than two factors (e.g., elevated CO_2 and increase in temperature). Most experiments test one global change factor. Single-factor experiments do not, however, provide us with the information needed to deduce the magnitude of long-term ecosystem responses. A few experiments have tested three factors (e.g., varying levels of CO_2, temperature, and O_3). In those, the three single effects are analyzed, the three two-way interactions are analyzed, but only one three-way interaction is analyzed. This is mainly due to the complexity of setting up and analyzing such experiments, and the statistical power of such experiments may be poor (Leuzinger et al. 2011). When multifactor experiments are established, they help in deciphering ecosystem response, but they lose much of their ability to make inferences about underlying and interacting mechanisms (Leuzinger et al. 2011). Experiments are also restricted in time. Very few large-scale change experiments have been maintained over 10 years (only two FACE sites), despite the knowledge that the effects of drivers, like the effects of elevated CO_2, may diminish over time (Hättenschwiler et al. 1997) and that forest longevity extends far beyond 10 years.

Experiments are spatially restricted. Laboratory findings may, for example, help understand processes but they do not reflect the reality of actual forest responses. In reality, when longer time periods and larger spatial scales are considered, this inevitably implies a growing number of processes acting on the system. For example, if the carbon or water cycle is studied at the leaf level, many processes are missed that are taking place in other parts of the plant such as symbiotic mycorrhizae or interactions with competing plants and animals. Therefore, if the aim of an experiment is prediction of a net ecosystem response, the experiment should be conducted in as near-natural conditions as possible (Leuzinger et al. 2011). There seems to be a dampening effect when small-scale or single-factor experimental responses are applied at larger scales. **Figure 6**, taken from Leuzinger et al. (2011), shows the example of the measured response to elevated CO_2 at the leaf level and at the whole-plant level. The WUE response to elevated CO_2 at the leaf level is much larger (<25%) than if the same response is evaluated at the tree transpiration level (<14%), and again, at yet coarser scales, the change in WUE measured as runoff is much smaller (<3%) at the catchment level (Körner et al. 2005; Saxe et al. 2001; Ellsworth et al. 2004).

Figure 6 clearly illustrates a scaling issue. There are many more processes influencing measurements at coarser scales, and some processes may even cancel each other out, making interpretation of the results difficult, particularly if all the processes are not identified or their responses are not understood. For example, the increase in WUE of 25% in **Figure 6** scenario did not result in a 25% increase in WUE for the whole tree. This may be due to other processes being adversely



Water savings in a temperate deciduous forest under elevated CO_2

Reduced stomatal conductance
Reduced tree transpiration
Increased catchment runoff

TRENDS in Ecology & Evolution

Figure 6 Case study at the Swiss Canopy Crane forest FACE site: 11 temperate broad-leaved trees were subjected to 550 ppm CO_2 during 8 years near Basel, Switzerland Leuzinger S., Y. Luo, C. Beier, W. Dieleman, S. Vicca, and C. Körner 2011: *Do global change experiments overestimate impacts on terrestrial ecosystems?* Trends in ecology & evolution **26** (5), 236–241. Shown are results from studies on water use of CO_2-treated and control trees (proportional change in treated compared to control). At equal microclimatic conditions, the percentage reduced stomatal conductance corresponds approximately to the percentage reduced transpiration. The larger the spatial perspective of estimating water use under elevated CO_2, the smaller the response compared to the control scenario. One explanation for the observed phenomenon is the increasing number of relevant processes acting at larger scales (e.g., soil and atmosphere feedbacks, plant–animal interactions, and competition).

influenced by elevated CO_2 (as opposed to positively for WUE) and requiring just as much or more water in absolute terms than in an environment without the CO_2 increase. As the scale gets coarser, the number of processes that are interacting with water use increases. The same is true for the production of photosynthate.

Scaling issues are also important to understand when dealing with different sources of data. In some cases, it is necessary to step back to see the pattern (e.g., with satellites), such as when the signal of large-scale climate patterns such as the Pacific Decadal Oscillation is sought. Conversely, a finer scale may be more appropriate when temperature seasonality effects are sought.

Models have been able to provide some of the information needed to evaluate the responses of ecosystems to changing environmental conditions. They are much less limited by data than experiments, and because of this are not bound by the same inference problem. Models, however, are limited by the information and structure that we impose on them when they are created. They are, by definition, a simplification of an ecosystem. Ecosystem-process models usually incorporate the processes that we know, and quantitative models rely more on response observations (Cramer et al. 2001; Luo and Weng 2011). Similarly, climate models that operate at global scales are a simplification of global circulation, perhaps omitting components that may prove to be essential.

4.12.3.1.2 Knowledge Gaps

It is common practice to extrapolate results from environmental change experiments through either space or time or both in an attempt to integrate all the available knowledge into models and large-scale estimates. Our present limitations in the scaling of processes or their responses affects our ability to estimate forest productivity even for the processes that we mechanistically understand well like photosynthesis – Farquhar described the physical process of photosynthesis at the molecular level in the 1980s (Farquhar et al. 1980). There are, however, processes that are much less understood and also those that affect our productivity estimates, e.g., portions of tree respiration remain unclear. The observations of tree mortality quantitatively linked to drought events are accumulating, but the processes that cause drought-induced tree mortality are still debated (McDowell 2011; Sala et al. 2010; Hartmann 2011) as neither catastrophic cavitation nor carbon starvation is presently well supported. This later process has a direct effect on productivity especially when we are trying to assess the effects of changing conditions, which include an increased probability of drought in many locations. Other unknowns include the effects of changing environmental variables on within-population genetic variability. Genetic variation has been shown to be uninfluenced by climate for some species (Hoban et al. 2010), while in other species, 50% of the variation was explained by climate variables (Normand et al. 2011). New hypotheses for processes acting on forest productivity are regularly being put forth and some may, with additional research and observational support, need to be integrated into our estimates of productivity; for example, a recent article identified 'supertrees' as merge individuals with higher productivity, a process that was observed in harsh environments (McIntire and Fajardo 2011). Physiological mechanisms are not alone in affecting productivity. Economic impacts can also be important and there are still few studies that can be regarded as fully integrating ecological and economic impacts. This is mostly due to our limited knowledge of the global implications of social and economic adaptation to the effects of climate on forests. These missing pieces of information should not prevent the integration of all known processes, but need to be identified so that their impacts (although not quantified) can at least be minimized or recognized when assessments are performed.

4.12.3.1.3 Compounding and Feedbacks Effects

Long-term ecological responses to environmental conditions are strongly regulated by slow processes such as changes in species composition, carbon dynamics in soil, and long-lived plants as well as the accumulation of nutrient capital. Changing conditions may or may not change the speed at which these slow processes occur, but many compounding and/or feedback effects have the potential to drastically change the forest landscape and, consequently, forest productivity. The dampening effect of upscaling small-scale experiments (as in Figure 6) means that both beneficial (e.g., a stimulation of plant growth under rising CO_2 or warming) and negative (e.g., reduced plant growth in response to drought or cooling) effects might be more or less dramatic than expected at larger scales and dependent on what changes concurrently take place. Genetic adaptation and traits variation may dampen the signal of large-scale responses be it through space or time. If the experiment portrayed in Figure 6 were to be maintained over a long time period and over a larger area, all leaves in a landscape could potentially adapt to having fewer stomata (and therefore increased WUE). In turn, transpiration for the whole region would be reduced and that, in turn, would further affect the environment by again affecting the leaves. Even the effect of large-scale disturbance will eventually be dampened through time since trees most probably will recolonize the post-disturbance site. Potential negative consequences of feedbacks come from large-scale ecosystem disturbances such as fires (Mildrexler et al. 2009). Large fires have major impacts on the global carbon cycle because large pulses of CO_2 and other trace gases from terrestrial biomass loss are emitted to the atmosphere during these events. An increased frequency of fires could positively feedback to radiative warming by releasing carbon into the atmosphere, but would also negatively feedback by increasing the surface albedo (Goetz et al. 2007). The rate of burn may not exceed historical bounds for certain regions but the compounded effects of increased fire incidence and forest management combined with increases in burn rate may result in large impacts on forest productivity. The loss of productivity in the white spruce stands of interior Alaska appears to result from the same type of compounding effect. The drought-induced decreases in growth in white spruce in Alaska have occurred in concordance with an increase in disease and insects occurrence, a warming and thawing of permafrost, and an increase in wildfire with postfire recruitment of deciduous species (white spruce seedlings seem to be more vulnerable to dry conditions), possibly fundamentally changing this forest type. Finally, even if a positive response of a given species is sustained over time (e.g., temperature-induced increase in productivity), shifts in species composition have the power to reverse initial trends.

Identifying potential sources of error in estimates of productivity is important since these estimates are the basis for our assessment of the potential effects of changing climatic conditions. To date, we have mentioned the scaling issues of known processes, unknown processes, and potential compounding and feedback effects. In addition to these factors, we must remember that often models need to be simple to be useful. This leads to the exclusion of known factors affecting productivity in many models, such as not integrating the effects of development change or history in current large-scale estimates of productivity (Albani et al. 2006) or not including functional traits together with their effects on the patch and size structure of vegetation in dynamic vegetation models (Falster et al. 2011). Based on global climate model simulations, we often attempt to incorporate drought events, but the length of drought, which has an important effect on productivity, is usually not skillfully modeled (Grant et al. 2006) and neither is fire intensity. Multimodel predicted scenarios of the twenty-first century fire severity are scarce and also have no demonstrated skill even in a hindcast mode, and the stand-typical response to severe fire weather is rarely taken into account.

4.12.3.1.4 Changing Relationships

Much of our understanding of forest productivity comes from existing forests and past experiences. Tree-ring data are the foundation of dendroclimatology studies where past climate data are reconstructed from tree-ring widths. But, relationships that may have been stable in the past are not necessarily maintained in a changing environment. Some speculate that we may be presently seeing such a transition within some northern forests, where divergence between dendroclimatology techniques of estimating past climate and measured temperatures is occurring. Repeated studies are now showing that the long-lasting consistencies between temperatures reconstructed from tree-width data are not consistent with temperatures recently measured by thermometers in northern forests (Briffa et al. 1998; D′Arrigo et al. 2008). Possible explanations for changes in this long-standing relationship include a factor that was not important in the past for forest productivity (or ring development) may now have become relevant, or perhaps a yet unknown physiological response to stresses or other factors.

Errors also stem from the input data: The global climate projections, even when statistically or dynamically downscaled to regions and local areas, when run in a hindcast mode for the past several decades, have shown no skill at predicting climate statistics on these spatial scales without tuning the model results using real-world observations at the spatial scale required for ecosystem function (e.g., see Stephens et al., 2010; Kundzewicz, Z. W., and E.Z. Stakhiv 2010). Skillfully predicting changes in these climate statistics is an even more daunting challenge. Yet, there are claims that we may already be in the higher portion of projected climate (Betts et al. 2011; Rahmstorf et al. 2007). If such conditions would occur, however, stands that in the past were thought to be resilient to change may no longer be. Conversely, other stable states may emerge (Johnstone et al. 2010).

Much of the uncertainty surrounding future productivity levels lie in the uncertainty of projected disturbances. There is high variability in most models' ability to estimate current distributions or conditions. Similarly, there is an inherently large uncertainty involved in making projections into the future. Interpolated long-term weather observations from local weather stations and gridded data products, which are the inputs for forest productivity models, yield biased projections (Cook & et al. 2010) since they are smoothed surfaces. Climate modeling has been the basis for modeling effects on ecosystems, but climate modeling has its own inherent uncertainties. For best results, these uncertainties must be quantified and propagated into simulations (Sushama et al. 2010). However, these model projections, at best, only provide a subset of what is possible in the future (Pielke and Wilby, 2012).

4.12.3.2 Risks

Despite these caveats and uncertainties, there is published evidence that allows us to identify some of the potential risks for forest productivity in future changing conditions. In forests with temperature-limited constraints on productivity, which includes high-latitude forests and high-altitude forests that are not constrained by water or that will receive additional precipitation along with the increase in temperature, productivity will increase with temperature. Changes in past productivity are thought to have been dominated by changes in N deposition. Conversely, changes in temperature and precipitation may be the major driver for future productivity. N deposition may still have a positive affect in N-depleted systems, but limitations in base cations, especially magnesium and phosphorus, may significantly affect predicted productivity in the future (de Vries and Posch 2010). Areas of high N deposition such as parts of Asia, the northeastern United States, and some parts of central Europe are at risk of productivity decreases due to changes in site nutrient status caused by high levels of N.

In a warmer environment, forests might become increasingly vulnerable to higher background tree mortality rates and die-off in response to heat waves and drought, even in environments that are not normally considered water-limited. Increases in the frequency, duration, and/or severity of drought and heat stress associated with climate could fundamentally alter the composition, structure, and biogeography of forests in many regions. All areas at present risk of drought could be at greater risk and neighboring areas might become water-limited.

Tree species may respond to drought by modifying certain traits such as WUE, which collectively may help dampened impacts of drought in specific regions. In the long-term, however, direct climate effects on forest physiological adaptation response or on forest dynamics may be small relative to autogenic successional processes or climate-related insect outbreaks (Kardol et al. 2010). Recent changes in temperature and precipitation have already resulted in changes in insect dynamics (Moraal and Jagers 2011; Raffa et al., 2008) and in forest pathogen dynamics (Sturrock et al. 2011). If temperature and precipitation change further, the effects of both forest diseases and insects will become more prominent and may result in changes in forest dynamics.

With increasing temperature and more variable precipitation, increases in fire frequency could contribute to increasing the level of atmospheric CO_2 and other atmospheric gases, representing a positive biogeochemical feedback, but also potentially a negative radiative feedback with a change in surface albedo. Figure 7 shows an example of a potential shift in forest biomes and a potential change in wildfire frequency away from a 1961–90 baseline, based on a selection of climate projections.

Further, the influence of soil conditions on tree migration is not well understood. A particular example of the impact of tree fecundity and dispersal adaptation has occurred in central Chilean Patagonia. Approximately 50–60 years ago, part of the temperate broad-leaved forest was burned to clear land. Much of the 2.8 million hectares of burned forest still remains as grassland today, mostly because of inherently low diversity with the two dominant tree species are not adapted to fire disturbance, nor are they adapted to wind dispersal. This example is not related to climate-induced changes, but illustrates well the potential impacts of a new disturbance when species are not adapted to that particular disturbance. In the Chilean Patagonia example, one cohort of native species has reestablished on the perimeter of the remnant old forest, but at now 50+ years of age, these trees are still not producing seeds. In a parallel effort to maintain soil stability on the mountainous region, forest managers have planted three North American pine species. To date, we know of no data indicating a successful recolonization of the burned area with exotic pine species. However, such occurrences may become reality in the future, as changing environments where fires and large-scale disturbances dominate forest changes, in places not adapted to fire. At broad scales, tree species migration would almost certainly occur with changing environmental conditions and increased disturbances. However, local and regional soil and site properties combined with species fecundity response to changing conditions, and the specific species' ability to disperse seeds, may dictate their migratory response.

4.12.4 Adaptation/Mitigation Options

Determining the possible adaptations of a particular site or region requires the amalgamation of known information across scales and recognition of the unknowns and their associated uncertainties. Probability of abiotic changes (temperature, precipitation, CO_2) can be generally deduced from existing information from the historical record, recent paleorecord, extreme events, and climate model scenarios for almost any forested site. Vulnerabilities of services provided by forest can be identified by combining what is known of these larger scale forcings with the specific conditions of the site or region. The capability of forest ecosystems to adapt depends on forest characteristics, the extent of the environmental changes, and

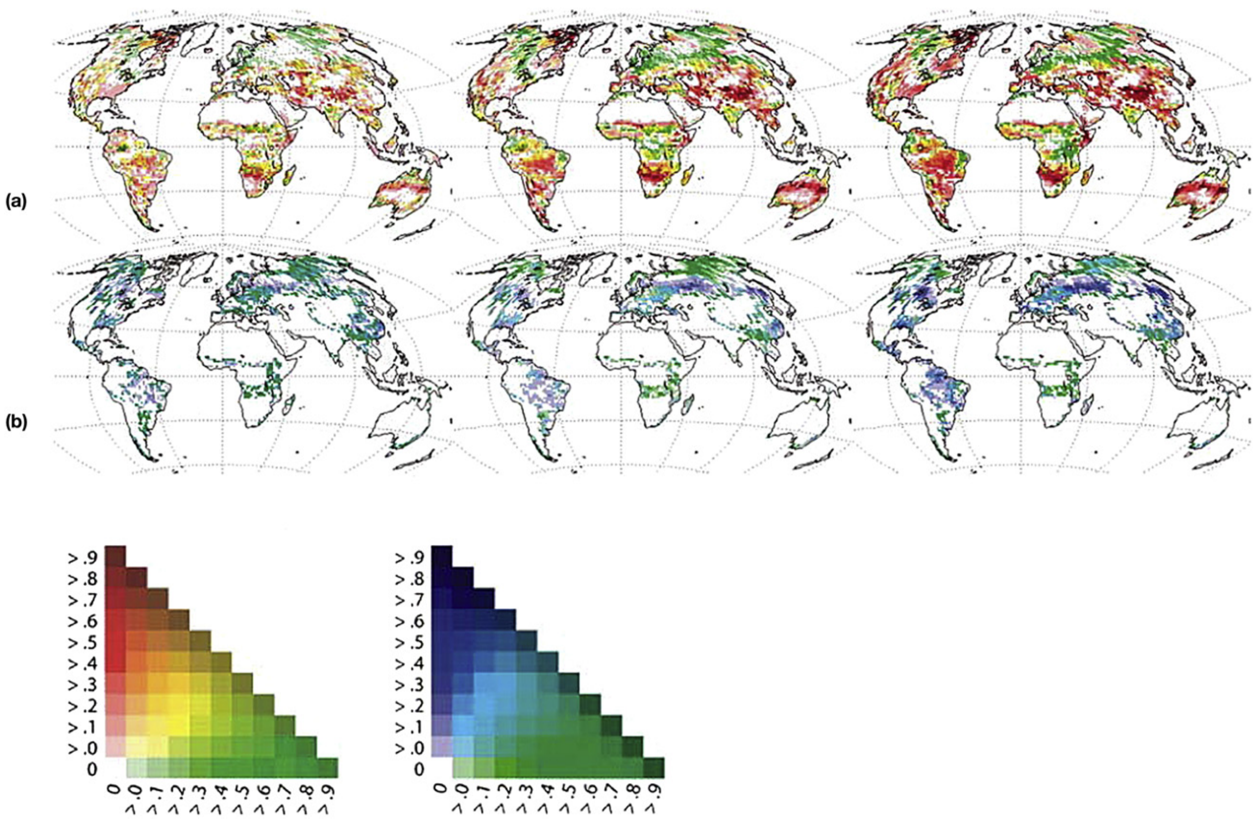

Figure 7 Results from modeling projections based on global circulation model projections Scholze M., W. Knorr, N. W. Arnell, 2006: *Prentice IC: A climate-change risk analysis for world ecosystems*. PNAS **103** (35), 13116–13120. Probability of exceeding critical levels of change between 1961–90 and 2071–2100 for wildfire frequency (a) and of a change in biome from forest to nonforest (b). For wildfire frequency, critical change is defined where the change in the mean of 2071–2100 exceeds $\pm 1\sigma$ of the observed (1961–90) interannual variability. (a) Wildfire frequency (red, increase; green, decrease). (b) Biome change from forest to nonforest (blue) or vice versa (green). For wildfire frequency and biome change, colors are shown only for grid cells with <75% cultivated and managed areas.

the socioeconomic factors determining the capability to implement planned adaptation. A variety of psychological, social, and institutional barriers to adaptation are exacerbated by uncertainty and long timeframes, with the danger of immobilizing decisionmakers. Complexity and uncertainty can be reduced by a systematic approach to categorizing the interactions between decision lifetime, the type of uncertainty in the relevant drivers of change, and the nature of adaptation response options (Warren 2011).

The following section provides basic knowledge about how forest might adapt to changing environmental conditions. A general framework is presented that permits the integration of the larger scale and local factors delimiting the range of possible adaptations for a specific site. This framework is one management avenue for the uncertainty inherent to changing conditions. Finally, this chapter ends by providing examples of possible mitigation actions and identifying some specific research areas that would reduce the uncertainties associated with selecting mitigation options.

4.12.4.1 Possible Adaptations

Adaptation to changes may happen in many ways. Individual species might adapt through phenological and/or genetic changes and/or might shift their distribution. Adaptation may also occur through a modification of trees, plants, and organisms associations. Different species mixes may emerge with the new environmental conditions. Some adaptations may reduce productivity and ecosystem services that forests presently provide, others may increase productivity, and some may maintain their present level. There are very few ecological processes that are driven by one factor. Forest growth and productivity represents a combined record of species genetic and environmental forcings, one of which is climate. Phenological adaptations occur when the climate-related stressor is within the response envelope of the species such that individuals can adjust behavior, morphology, or physiology to accommodate the change. For example, some species have already adapted with early spring flowering to match the earlier spring onset, and as in the elevated CO_2 experiment (**Figure 6**), some are able to vary their stomata number in elevated CO_2 conditions. These adaptations do not involve genetic changes. Changes in gene frequencies are caused by natural selection and may emerge as an adaptive evolution. This type of adaptation is more common in fast growing organisms or organisms that have short life cycles. Forest insects may already be showing some genetic adaptation to changing conditions. Forest trees are long-lived organisms and the effects of changing environmental variables on within-population genetic variability are not yet known. There is no evidence of genetic adaptations in forest trees to the environmental changes presently occurring.

Species may shift their present distribution in response to changing environmental conditions. Range shifts have already been reported. More drought-tolerant species seem to be shifting to regions with increasing drought conditions, like in the Mediterranean region. The northern tree-limit is reported to have already moved north in boreal Alaska and western Canada, and temperature-limited altitudinal tree lines have also been observed to climb. Species movements would be likely with an increasing intensity of environmental changes. This could lead to new combinations of species with new forest dynamics behavior. Invasive species are also more common, could be part of the new combinations, and could even be part of new stable states in forest dynamics. Phenological adaptations, genetic changes, and species shifts may all be concomitantly occurring. Monitoring and reporting changes in species distribution and combination and in phenological adaptations will be the key to seeing which of these is or is not occurring and the extent of each adaptation.

4.12.4.2 Decision Framework

Productivity–climate relationships often vary at relatively small spatial scales (Nakawatase and Peterson 2006). Each location has a set of conditions (local and global) that has resulted in the present state of forest productivity. Local conditions are paramount in determining how changes may affect forests, but local relationships may also be overpowered by large-scale events. **Figure 8** presents a framework that combines both local and global conditions to delimitate the possible adaptation outcomes. From these possible adaptation paths, the effect of changing conditions on forest productivity can be evaluated and management options identified.

Each location can have its own set of probable outcomes. In a location where the past drivers of productivity have been the physiological responses to change, local authorities and scientists may evaluate the possibilities of other forces becoming the dominant drivers of productivity (such as fire or insect disturbances). This evaluation can be in the form of a likelihood based on the current conditions of the system and current knowledge (Box 1 in **Figure 8**) and the possible change (Box 2 – **Figure 8**). This may lead to choosing an adaptation option to minimize the probability of fire occurrence, while still anticipating the physiological responses and monitoring for any signs of change. The IPCC provides a subset of possible future climate which has been regionalized for many parts of the world. As a result, a subset of plausible climatic changes (Box 2 – **Figure 8**) have been based on these regionalized projections, they can be a first step, along with the historical record, recent paleo-record, extreme events, at planning for possible future scenarios and adapted as improved projections become available.

Environmental change is only one of the possible stressors affecting forests. In this framework, the extent to which other stressors affect productivity can be integrated (such as over harvesting or where invasive species limit population size or growth). Some of the integration work has already been done for specific localities. Maps of species current distributions have been estimated for possible future conditions (Coops et al. 2007b, 2009). As well, some physiological modeling under a set of climate scenarios has also been performed (Boisvenue and Running 2010). Drivers of past productivity have been identified for many locations. Generally, it is thought that for many locations any forest management efforts would be overwhelmed by natural disturbances (Kurz et al. 2008), which may be the case in some locations. Places that have already shown loss of forest land due to concurrent decreased growth and increased mortality due to drought and fire events, such as the southwestern Unites States (Yuan et al. 2008; Ganey and Vojta 2011), may be limited in adaptation options for the region as a whole.

LOCAL FACTORS
RANGE OF POSSIBLE ADAPTATIONS
MANAGEMENT OPTIONS FOR MITIGATION

Figure 8 A framework for developing local adaptation and mitigation options for management of forest productivity.

However, localized strategies to minimize the effect of drought and prevent fire may be able to maintain a viable forest in specific locations within the generally affected area. Many forests could be managed to adapt to changes in environmental conditions and minimize the undesirable effects of expected increases in tree mortality due to insects (Sturrock et al. 2011). In some locations, change may involve increases in intense rain or wind events, and selected strategies may include minimizing landslides or windthrow. In other areas, possible adaptations will be relatively simple, at least in the short-term assessment. For example, where a single climatic limiting factor clearly dominates, such as low-temperature constraints on the growing season at high latitudes or water limitations in dry forests, plant responses are fairly predictable. Generalist species are also more likely to do better as they are less restricted in the combination of factors required for their survival and growth. Hence, if the present species composition is dominated by generalist species, the probability of maintaining similar levels of productivity may be quite good. Other synergic factors may compound the effects of changing conditions on the ability of a species to adapt to changes environmental conditions. A simultaneous increase in fire frequency and the harvest rate might seriously compromise overall productivity. This approach assumes that localities can be flexible and adapt their selected options as the environmental conditions change and/or as the knowledge of how the system may react, increases. Unfortunately, few political organizations are presently that flexible.

4.12.4.3 Mitigation Actions

The main tools for mitigation of undesirable effects of changing conditions on forest productivity are vegetation management and mobility of services. If some options are not socially acceptable, and can be avoided, management-driven mitigation actions can be derived. If the loss of productivity is unavoidable, services provided by this specific forest may possibly be extracted from other locations (e.g., wood products) but other less-mobile services may be lost. Assisted migration programs exist. In parts of the United States and in western Canada, more southern ecotypes of trees are being manually replanted in areas where the anticipated conditions are likely to match that of the ecotype. Provenance manipulation (Griesbauer et al. 2011) and genetic and silvicultural approaches to increase adaptive capacities and to decrease climate-related vulnerabilities of forests can be based on ecophysiological knowledge. In northern latitudes, much of the genetic variation in trees revolves around cold hardiness dormancy timing and frost tolerance, so moving trees to higher latitudes or elevation may be acceptable if the regional climate warms over decadal and longer time scales. A species' distribution since the last glacial maximum may be a good indicator of a species' ability to adapt with wide-ranging species being more likely to exhibit more plasticity in their traits. Areas of increased aridity would most probably loose some leaf-area carrying capacity. Planting at reduced density in these sites may be a viable solution. For sites with increases in large-scale insect epidemics and large-scale wildfires, increasing thinning and vegetation harvesting may be an option to reduce stress and fire probability. Such an increase in biomass harvesting may even be paired with the use of the extracted material as biofuel. Once the range of possible adaptations is defined, if maintaining forests on sites is a viable option, most management actions should probably be aimed at increasing the forest resistance and resilience. Because species responses to environmental change are and will be largely idiosyncratic, managing for resilience will require monitoring and flexibility in management interventions. Indicator species and a lookout for new or invasive species may help in resilience monitoring.

4.12.4.4 Reducing Uncertainties

The uncertainties inherent to changing conditions can be diminished by conducting research, assessing risks, and linking results to forest policy and planning. Global-level monitoring efforts are essential to provide examples of local adaptation strategies, but also to prevent (or anticipate) large-scale losses and reduce uncertainties. For example, it is not yet clear if forests are losing genetic diversity. In high diversity areas like the tropics, monitoring will be required to ensure that we do not lose important genetic material (Hoban et al. 2010; Normand et al. 2011). The varied responses that have already occurred as well as our knowledge gaps about processes and how they combined through scales, justify the need for global monitoring (Körner 2004; Bugmann and Bigler 2010).

There are other identifiable ways to reduce uncertainty. First, at the stand-scale, some of the uncertainties in productivity estimates can be substantially reduced with a better quantification of fine-root turnover and litterfall, which are the two dominant NPP components, particularly in the later stages of stand development (Chen et al. 2002). Some work is underway for quantitative estimates but these must be consolidated and made available for modeling exercises. Second, there are currently conflicting results between species niche modeling and process modeling. Niche modeling predicts a decline in productivity, while ecophysiological modeling predicts more of an increase (Keenan et al. 2011). A new synergy between niche- and process-based models is urgently needed in order to improve our predictive ability of productivity. Third, the pinpointing of processes behind drought-induced mortality would also contribute to much improved predictions of vulnerability (Lines et al. 2010; McDowell 2011), and would help to incorporate drought effects into global carbon cycle models (van der Molen et al. 2011) to account for some of the feedbacks effects. Fourth, N-feedback effects should also be included in global-scale models because N is now emerging as a pivotal factor in response to global change (Norby et al. 2010). Fifth, disturbance modeling cannot be ignored in projections of forest productivity (Flannigan et al. 2005; Fleming et al. 2002). Here again, much information is available and many sophisticated modeling approaches have been applied to disturbance projections, but these projections need to be incorporated into forest productivity projections. Sixth, more of the uncertainty in climate modeling, the main input to productivity projections, needs to be taken into account in forest productivity modeling (Sushama et al. 2010, Pielke and Wilby, 2012).

Processes such as photosynthesis, respiration, plant nutrient requirements, transpiration, water relations, and other factors affecting plant growth have often been separately addressed. This has led to a better understanding of the individual processes, but integration should now be the focus of current research to show clear relationships between processes and to better understand the scaling issues necessary for assessment of the impacts of a changing environment. More linkages between experimental results and monitoring tools may compensate for some of our knowledge gaps (Polly et al. 2011; Norby and Luo 2004). Long-term global-change manipulative experiments, especially in high-priority ecosystems such as tropical forests and high-latitude regions, are essential to maximizing information gain concerning future states of the earth system. One such research effort is underway with the National Aeronautics and Space Administration in the United States (http://cce.nasa.gov/terrestrial_ecology/scoping.html).

Models are essential for assimilating data from long-term experiments and process studies, with information from long-term observations, surveys, and space-for-time studies along environmental and biological gradients. Linking data across scales has already begun (Running et al. 2004; Van Tuyl et al. 2005; Reichstein et al. 2007; Scurlock and Olson 2002; Verstraeten et al. 2006; Coops et al. 2007a; Pan et al. 2006). With new and freely available satellite data (Zhao et al. 2005) many more cross-scale linkages can be developed (Mildrexler et al. 2009). Such advances will help reduce modeling uncertainties and may contribute to deciphering cross-scale effects as well as correcting existing biases (Simic et al. 2004; Smith et al. 2011). Any climate mitigation actions will require regular reassessment and reorganization as environmental conditions change and as more or better information on the processes that lead to forest productivity becomes available. In this context of a constant flow of new information and where new analytical tools are constantly becoming available, scientists, policy makers, and land managers need to jointly develop adaptation and mitigation approaches to forested land management.

4.13.1 Introduction

Grassland systems are extensively present across the globe and are a critical source of ecosystem services to societal groups on many continents. These systems are characterized by their arid and semiarid environments where rainfall tends to be too variable or evaporative losses reduce water availability to reliably support cropping systems or substantial forest cover. A number of grasslands worldwide have developed land-use practices to accommodate the variable rainfall patterns, and seasonal and spatial patterns of forage production displayed by the nomadic pastoral systems practiced in Asia and in Africa. The Americas, in contrast, have more sedentary forms of livestock production that are implemented more and more in other regions of the globe. Grasslands and other semiarid systems, globally, support over 1 billion people. These pastoral systems are dependent on grassland ecosystem services, including forage production, wool, skins, meat, and dairy products, and in many systems provide critical biodiversity and land and water protection services that serve to maintain pastoral livelihoods. Precipitation variability and associated drought conditions frequently experienced in these grassland systems are key drivers of these systems.

Due to the inherent climate variability of grassland ecosystems, they have a complex relationship to vulnerability, which depends on the scale of interest and the scope of the drivers of change. Vulnerability is defined as the degree to which a system experiences harm due to exposure to a perturbation or stress (Turner et al. 2003a,b) and can be evaluated by assessing the sensitivity and adaptive capacity of social–ecological systems to exposure to external pressures (Sietz et al., 2011). As one evaluates the vulnerability of grassland systems, there are considerations of both the biophysical nature and the social–ecological system perspectives that need to be considered. In addition, these biophysical nature and social–ecological perspectives influence the manner in which exposure and sensitivity of the system will affect the system dynamic. The ability of the social–ecological system to respond to these impacts, as determined by the exposure and sensitivity factors, will depend on the adaptive capacity of the system and the available capital assets available to the community. The resilience of the system or the adaptation actions taken under a particular stress will be determined by a combination of these factors, which vary over time and space even within a particular system under consideration. Grassland systems tend to have higher levels of vulnerability since the exposure to climate effects in numerous regions is becoming more evident, and the sensitivity to changes in moisture can lead to threshold changes in a number of social–ecological features of the pastoral and grassland systems across the globe. In addition, in many of the regions of the world the range of adaptive capacity has been altered in ways that reduce the ability of the system to adjust or to accommodate the changes these systems are facing.

The biophysical vulnerabilities are more apparent and more readily evaluated. The social–ecological view more explicitly incorporates the human dimension into the evaluation of vulnerability of the system (Kasperson and Kasperson 2001; Robinson and Berkes 2010), especially related to livelihood strategies undertaken by different communities that affect both the grassland ecosystems, and characterizes the adaptive capacity of the system to cope with change. The manner in which these climate and social–ecological factors interact across various dimensions of space, time, and social characteristics of grassland systems define different levels of vulnerability to climate and other stressors. Impacts of these changes are unequally felt throughout a community or region (Galvin et al. 2004). The level of impacts to the social–ecological system will depend on interaction between impacts on natural and human, social and capital assets of the system that groups or individuals rely upon most closely to determine decisions of livelihood strategies (Vogel et al. 2007; Galvin, 2009). Although various communities may face similar risks, they may not be equally vulnerable.

There are a number of methods to measure a group's vulnerability (Robinson and Berkes 2010; Sietz et al. 2011). Adger et al. (2001, 2003, 2006) describe vulnerability assessments that include measures combining poverty indicators with a measurement of the diversity of resources, such as household income, education level, health of children, and other factors. Other assessment methods of vulnerability combine a suite of sensitivity indicators relative to socioeconomic variability, such as food security, ecosystem,

http://dx.doi.org/10.1016/B978-0-12-384703-4.00417-2

settlement/infrastructure, or human population health conditions (Moss et al. 2000). Measuring both ecosystem vulnerability and indicators of human vulnerability provides information on the interaction between the social and economical vulnerability of populations and the degree of resilience of the ecosystem.

This chapter explores these related factors across different grassland systems to illustrate both the biophysical aspects and the social–ecological characteristics of vulnerability of these systems. The analysis provides insights to the robust adaptive capacity these systems possess under certain situations of environmental stresses and the fragility under conditions of multiple stresses or when thresholds are crossed. These threshold changes can prevent inherent processes and social–ecological structures to adequately respond to stresses and may lead to fundamental system changes.

4.13.2 Background

Grasslands around the globe occupy ~40% or about $55.5 \times 10^6\,\text{km}^2$ of the Earth's terrestrial surface, excluding Greenland and Antarctica (Olson et al. 1983). Land-use intensification due to grazing and cropland conversion in a number of areas around the world has had global-scale impacts on carbon, water cycling, and dust aerosols (Neff et al. 2008). These impacts have local and regional impacts on human well-being and grassland productivity. Precipitation and soil water are key parameters controlling ecosystem structure and function of grassland ecosystems in arid and semiarid regions. Grassland ecosystems are particularly sensitive to the balance among factors controling water availability, including increased temperature, which directly affects evapo-transpiration (ET), changes in precipitation patterns, and altered soil water storage and elevated atmospheric CO_2 concentration (Ojima et al. 1996; Owensby et al. 1999; Morgan et al., 2001, 2004a,b, 2011). Land-use impacts have historically impacted grassland systems throughout its range in Eurasia and Americas due to the fertile soils and ease of conversion to croplands. In the coming decades, the combination of changing land use and increased aridity could enhance dust emissions and destabilize grasslands (Reynolds et al. 2001; Neff et al. 2005), unless adaptive management strategies can be employed to mitigate ecosystem responses.

In these grassland systems, plant productivity and water cycles are tightly coupled (Ojima et al. 1993; Sala et al. 1996), but this linkage depends in part on the plant functional types (Peters 2002) and can be disrupted by land-use changes and invasive species. For instance, warm season (C4) grasses take advantage of summer moisture associated with monsoon rains. Modeling and field observations suggest that transpirational (T) water loss (T/ET) is greater from grasslands than shrublands in the southwestern United States (Peters 2002; Emmerich 2007). The seasonal expression of plant metabolism and rooting depth accessing soil moisture determines some of the differences between grass and shrub functional types and differences in plant cover (% bare ground), which controls the differences in evapotranspiration. Climate affects the distribution of plant functional types that has an effect on the delivery of ecosystem services. In addition, the vulnerability of these systems may be altered by the changes in plant functional types due to changes in moisture relationships of the vegetation relative to changes in temperature and evapo-transpiration.

The sensitivity of these grassland systems to climate is associated with the lack of adequate reserves of water, low soil nutrients, and the low vegetative cover (Hulme et al. 2001; Olesen and Bindi 2002). These characteristics make these grassland ecosystems to be among the earliest ecosystems to exhibit the effects of changes in temperature and moisture (Ojima et al. 1993). In addition, vulnerability to climate variability and directional climate change of these ecosystems is accelerated by human-induced land-use changes (Ellis and Galvin 1994; Schlesinger et al. 1990; Reynolds et al. 2007). There are several ways in which changes in local and regional climate may affect ecosystem function and structure of grasslands. These effects may occur through interactions of changes in regional climatology and direct human actions including grazing management, biogeochemical direct CO_2 effects, and structural changes resulting from woody expansion or bush clearing (Morgan et al. 2001, 2011; Archer et al. 1995, 2001; Hibbard et al 2003; Parton et al. 1994).

These grassland social–ecological systems have developed to accommodate the variable rainfall patterns and extensive forage production across landscapes. Nomadic pastoral systems have emerged across all grasslands as an effective grazing system to capture dispersed ecosystem services in space and time across vast landscapes. Recently, transition of these nomadic practices has given way to more sedentary forms of livestock production and in some regions have altered the delivery of ecosystem services. In addition to these primarily pastoral systems, mixed crop systems have also developed where opportunistic crop production is deployed to augment both human and livestock food supply (Seré et al. 1996; Bouwman 2005). Changes in land use arise from changes in demographic patterns, economic incentives, market demands, production goals, and policy issues related to land ownership and market access. These factors vary across the globe; for instance, in the Eurasian steppe the recent political reorganization has led to recovery of some of the grasslands, in part due to the collapse of supporting infrastructure developed under Soviet management and the resulting decline in livestock numbers throughout the region (Ojima et al. 2004; Chuluun et al. 2005, 2008). Drought experienced during the late 1950s coupled with increased human population levels and policy decisions in Inner Mongolia have led to large scale land degradation and human suffering. Land degradation in this region of China continued into the 1990s due to intensification of grazing and cropping leading to more drastic policy regulations to reduce these pressures on the land in recent years.

It is generally difficult to separate the effect of human-induced land degradation from the effect of climate including drought. The grazing pressure in these systems is not adequately reduced at the time of onset of a major drought, and these grazing levels accelerate the degradation of the grassland system as the drought conditions persist. The combination of drought conditions and grazing pressure can lead to desertification and loss of grassland components of these landscapes.

In general, grasslands are dominated by perennial grasses and woody plants. Desert or desertlike environments are characterized by a greater presence of woody canopy cover and a replacement of perennial grasses by annuals. Grazing pressure alone can result in a switch from grassland vegetation to more woody components dominating the landscape (Archer et al. 1995, 2001). Soil erosion rates may increase as plant cover decreases leading to loss of productive potential – a process that may be irreversible, or nearly so. The rate of transition is almost always exacerbated by intense human use of the land, as occurs in most grassland and savanna regions (Neff et al. 2005, 2008; Seitz et al. 2011; Reynolds et al. 2007). Grassland degradation can thus occur through both functional (e.g., reduced primary productivity) and structural (e.g., from perennial to annual grasses or to woody encroachment) change.

In summary, social–ecological grassland systems are very sensitive to climate. First, productivity and nutrient cycling are closely tied to climate and could appreciably change with altered climate. Fairly small climatic changes could induce structural changes over large areas of grasslands. These structural changes may result from degradation of grasslands and lead to a dramatic reduction in ecosystem services and increase the vulnerability of the social–ecological system. In addition to these biophysical interactions, the sensitivity to market demands also contributes to changes in land-use practices. If these land-use practices lead to intensification of grazing levels or land-use conversion that exceeds the ability of ecosystem services to maintain or support ecosystem production, then the resilience of the system may be compromised beyond its ability to maintain grassland components of the system and may collapse (Walker and Salt 2006; Reynolds et al. 2007). When we look at the impact of climate on grasslands, it is important to assess the impacts in conjunction markets, policies, and other human activities.

The following case studies are presented to illustrate the interplay of biophysical changes under differing social–ecological systems in the Central United States (Great Plains), Eurasia (primarily, Mongolia), and East Africa.

4.13.3 Great Plains

The US Great Plains covers an area of 1.3 million km^2 in the Central United States and was historically predominantly grasslands. Large numbers of ungulates coevolved in the extensive grasslands of the Great Plains with large herds of bison, elk, and pronghorn observed across the landscapes of the Great Plains in the 1800s. Fire is a major feature in the more mesic regions of the Great Plains, with the tallgrass prairie burning, historically, every 2–3 years (Hulbert 1986; Ojima et al. 1994).

Native American populations occupied these grassland systems for thousands of years. Now, however, much of these grasslands have been taken over by settlers since the late 1800s and have converted these grasslands to croplands or large ranches. The Plains are characterized by a temperature gradient from north to south and a precipitation gradient from west to east. Annual average precipitation ranges from 200 mm in the west to approximately 1100 mm in the east and southeastern portion of the range and can be highly variable from year to year. There is strong seasonality, high variability, and frequent extreme events in the Great Plains including droughts, floods, hail, ice storms, heat waves, tornadoes, and blizzards.

Currently in the US Great Plains, the grazing industry is based on industrial and private ranching. The size of ranches is often quite large, and when cattle are pulled off of the range they are often finished at feedlots where they are grain-fed. Many ranchers also grow crops, some for sale and some for feed, so separating livestock operations from cropping operations is often difficult in the Great Plains.

Land managers in the Great Plains are concerned about a variety of factors related to climate variability and change, though often multidecadal changes in climate statistics is not the most important concern. More likely, other factors such as market or commodity prices, incentives, conservation policy, and social factors are considered in the decision making (Ojima and Lackett 2002). In fact, many operators in this region are vulnerable due to the declining economic returns from farming and ranching. Many land managers and households are operating on the economic margin, and small shifts in climate or markets may drive them out of business. There have been record numbers of foreclosures in the region in the past decade, and these farms are often being aggregated into larger operations. This is leading to population declines in the region, especially of the younger segment of the population who find it difficult to maintain a livelihood. This results in creating an older population demographic, overall, in the region. These changes in the size of operations and the demographic impacts that result have an adverse effect on the social structure of these rural areas. These trends have put pressure on rural areas, leading to a stressed system where rural towns may have problems providing adequate social services for inhabitants due to declining population numbers, tax bases, and rural infrastructure.

In the Great Plains environment, variability in weather and economic dynamics results in enhanced uncertainty in land-use decisions and the social well-being of the region. The rangeland ecosystems have proven more vulnerable to changes in precipitation patterns during the past decade. Changes in climate statistics are being experienced in various ways, such as increased nighttime temperature, increased intensity of rainfall events, extended growing season, extended drought periods, and elevated atmospheric CO_2 concentration (Field et al. 2007; CCSP 2008a). Associated changes in vegetation structure due to droughts in the semiarid ecosystems affect grassland production and the extent of shrub cover affecting the forage availability in these rangelands (Hibbard et al 2003). The potential impacts of these changes include the modified vulnerability of farm and ranch families to climate and market stresses, the modification of crop and livestock production systems, impacted water use competition, changed water quality, expansion of weeds, pests, and diseases, a change in plant–animal communities, altered fire and storm patterns, changes in grassland ecosystems, such as species composition, disruption of pollinator relationships, tree mortality, enhanced vulnerability to drought conditions, and insect or disease outbreaks (Field et al. 2007; CCSP 2008a,b).

Seasonality is an important factor affecting land systems in the Great Plains. A change in the mean is not as important to the land managers as a change in variability or seasonal patterns of change. For example, hotter temperatures and less moisture during the growing season may dramatically impact range production. Other variables identified included summer droughts, winter storms, extreme ice storms, and temperature extremes. Changes in climate statistics that affect the frequency of these events would increase the exposure to these detrimental weather impacts and increase the vulnerability of these pastoral systems, which are financially operating on a narrow margin of success.

When strictly looking at range and livestock systems, there are a number of potential impacts identified (Morgan et al. 2001, 2004a,b, 2011; Ojima and Lackett 2002). First, forage production and quality will certainly be altered. Some of the changes may be beneficial, such as enhanced production under elevated CO_2, while other changes may be deleterious, such as the fact that the forage may be less nutritious (Polley et al 2002). Carrying capacity will be impacted and there will be vegetation shifts. Increased extreme events may lead to impaired performance of intensive livestock systems if livestock thermal thresholds are exceeded (Hahn and Mader 1997). There may be changes in the irrigation water supply, which has implications for the raising of feed for livestock (Ojima and Lackett 2002).

Coping strategies that farmers, ranchers, and other residents of the Great Plains may use to deal with climate include better preparation for extreme events and multiple year events, diversification of land-use practices in cropping and livestock systems in order to take advantage of opportunities and reduce vulnerabilities, researching new storage areas for water in case new storage locations are needed in the future under a changed hydrological regime, and increasing soil organic matter in order to increase water holding capacity and soil fertility (Ojima and Lackett 2002).

When managing ecosystem services for climate and employing adaptive management practices, a number of concepts are important to understand. First, the regional context of the change is important, for instance market drivers of cashmere, land tenure policies, and community governance of grazing land access. Second, no-regrets options, such as improving grazing systems to store more organic matter and improved soil moisture. These options make sense given current conditions and that potential future options should be established. Third, people need to be provided with alternatives for adaptation, based on the adaptive capacity. Fourth, communities should learn by doing and evaluate results along the way, making the process of adaptation an iterative process that provides community engagement. And last, the public must be kept informed of the implications of change.

Analysis of coping strategies to climate in the Great Plains indicates that various aspects need to be included in the decision-making process in developing adaptation strategies. These include the following: First, vulnerability needs to be studied in the local context and needs to be measured in terms of variability and extreme events. Second, the vulnerability of currently stressed sectors in the Great Plains could be exacerbated due to changes in grassland climate. Third, land managers in the Great Plains are concerned with changes in the environment, climate, and society, as well as economic considerations. Fourth, seasonal changes to snowmelt will likely impact water storage and delivery systems in the region and residents are very concerned about a clean and reliable water source. Fifth, soil carbon management is critical to coping with climate, and conserving and building soil carbon is seen as a 'win–win' situation. And last, technological and information transfers that may help residents do not always reach the stakeholders in a meaningful way.

Many ranchers want to be part of the solution to reduce risks from environmental change (Ojima and Lackett 2002). They also want to explore opportunities that may emerge due to changes in grassland climatology, and of course to be prepared for any negative shifts. Flexible no-regrets options may help many ranchers ride out the financial ups and downs that are the norm in today's market to stay in business. Coping strategies include better forecasting and preparation for extreme events and multiple year events, land conversion and changes in enterprise, new or improved grazing systems, efforts to understand pest and disease vectors, development of better communication at all levels (scientists, end users, and policymakers), and diversification of land-use practices in cropping and livestock systems.

Management strategies that lessen the impacts of the changing grassland climatology on domestic livestock and people in the Plains are needed. Strategies to reduce vulnerability of domestic livestock include changes of the mix of livestock raised, change of breeds of animals, change in genetics of livestock, change the seasonality of production (e.g., calving, lambing, weaning), and incorporation of technologies to reduce stresses and pest on animals. Strategies that may reduce livelihood vulnerabilities include diversification of operations and increased access to diverse landscape types. The adoption of public policies to deal with climate and the development of improved system-level management can also provide additional guidance to operators, which provide greater resilience to extreme events (possibly more frequent or longer) and include considerations for increased feed reserves, enterprise diversification, improved weather forecasting, increased water reserves, and tactics for dealing with hot temperatures in intensive livestock operations.

Overall, there are five points that characterize the Great Plains today (and reflect characteristics common to other regions around the world, as well):

1. Vulnerability needs to be measured in terms of variability, extreme events, and economics. Both the economics of implementing coping strategies and the seasonality of changes are important in assessing the vulnerability of people in the Plains.
2. Land managers in the Great Plains are concerned with changes in the environment and climate, as well as economic considerations. They are also interested in skillful climate forecasts for other regions that produce products that compete with products from the Great Plains.
3. Technological and information transfers do not always reach stakeholders. There is a communication gap that needs to be improved in order to keep stakeholders informed on plausible changes and options.
4. The vulnerability of currently stressed sectors in the Great Plains will likely be exacerbated. For the many farmers and ranchers in the Plains who are already on the edge, slight detrimental climatic changes could push them over the edge.
5. Seasonal changes to snowmelt in the Rocky Mountains may impact water storage and delivery systems. This has important implications for irrigation and stock water.

4.13.4 Mongolian Example

The Mongolian grasslands have a diversity of ecosystems, ranging from forest-steppe in the north to the Gobi desert-steppe in the south, and the steppe ecosystem dispersed in between. The Altai Mountains in the southwest, the Khangai Mountains, and the Khentii Mountains in north-central part of the country add to diversity of landscape, habitat, and resource availability. The Mongolian nomadic pastoral cultures occur as an emergent feature of the variable ecosystem dynamics of the arid and semiarid systems. These pastoral systems have adapted to variable environmental conditions responding to seasonally available resources across various landscapes ranging from river valleys, meadows, steppe, and mountain valleys. The emergence of hierarchical pastoral networks or cooperative groups based on a common location of natural resources or family relationships, as a complex adaptive system, increases the resiliency of these systems to climate variability.

Throughout history, nomadic herders in the Eurasian steppe have both formally and informally organized themselves, or have been organized, into a rich variety of societies. At the smallest level, livestock production has always been carried out around a range of customary institutions that perform social, political, and economic functions: the household, the camp, and the neighborhood. Throughout the period of radical changes that have occurred in the Eurasian steppe region, from feudalism through socialism to the emerging market system, these most basic of institutions have survived in one form or another in Mongolia.

Traditional pastoral networks evolved in the direction to increase human adaptive capacity to cope with climatic risks. Spatially large landscapes are critical in arid lands to offset climate variability with extreme events such as winter storm events (*zud*) and droughts. Interaction between ecosystems and nomadic land-use systems coshaped them in mutual adaptive ways for hundreds of years, thus making both the Mongolian rangeland ecosystem and the nomadic pastoral system resilient and sustainable.

In addition, the cultural landscape design of the nomadic pastoralists of Mongolia developed so that seasonal movement of livestock was coordinated among the various communities and tribes. The nomadic pastoral system took advantage of the winter forage areas of the mountains where snow was available for watering the livestock and the herders and winter forage available from the previous summer's growth. Movement to the valley as spring emerged took advantage of the early emergence of forage along streams, and later summer movements sought forage in valleys where moisture from seeps and springs provided good pastures.

These pastoral traditional networks have emerged with an understanding of the variability of resources in time and space and tend to maximize forage accessibility under these variable conditions in the Mongolian steppe (Chuluun 2000; Ojima et al. 2004; Chuluun et al. 2005; Chuluun et al. 2008; Ojima and Chuluun 2008). The most mobile herders are associated with drier parts of the steppe and the Gobi areas where nonequilibrium grassland ecosystem dynamics are observed (Fernández-Giménez 1999). The herders from these regions move to places where better rangeland conditions exist–especially during the summer season. Currently, their movements are constrained to administrative boundaries, rather than to the ecological extent of suitable rangelands.

The fragmentation of the cultural landscape due to political reorganization of the local political boundaries in the grassland systems of Mongolia has increased vulnerability and reduced the adaptive capacities to cope with climate variability of traditional pastoral systems. During the collectivization or *negdel* period between 1960 and 1990, herders were moving less frequently, but across longer distances with support from the centralized government providing mechanized transport (e.g., trucks and tractors). The pastoral collectives and the state assigned new administrative territories that cut across lines of traditional nomadic movements. Within these collectives were several smaller units or teams, which were the levels at which herding activities were allocated and was comprised of one or two households (Mearns 1993). Although these traditional functions may have been subsumed by the collectives, the customary institutions did not disappear altogether, as is demonstrated by the fact that many are now reemerging. However, herders still kept the traditional pastoral land-use concept. Herdsmen were commonly organized into collectives and were allowed only a small number of animals for private ownership (Sneath 2003). The provincial and national government established a strategy for short-term, long-distance moves (*otor*) to safeguard against drought and rangeland overuse. This strategy also served as a mechanism to fatten the stock in the summer and fall seasons. The collectives made all decisions over allocations of animals and specialization in tasks and species. Although these functions may have been subsumed by the collectives, the customary institutions did not disappear altogether, as is demonstrated by the fact that historic community structures have reemerged such as the 'hot ails,' referring to people from one river or one well, or people from one living area and is result of adapting to particular kind of environment in Mongolia, during the transition to a market economy (Schmidt et al. 2002; Janzen 2005; Schmidt 2006; Reading et al. 2006).

Negdels or collectives were dissolved with the privatization of livestock in the early 1990s. Since the decollectivization started in the early 1990s, pastoral movement became less frequent and shorter due to the lack of subsidies to maintain transportation for long-distance travel and preference to stay closer to settled areas and water source areas (Janzen 2005; Fernández-Giménez 2006; Reading et al. 2006). The higher concentration of livestock near settled areas and year-round use of riparian zones have led to deterioration of the rangelands (Ojima et al. 2004; Janzen 2005; Chuluun et al. 2005).

4.13.4.1 Current Conditions

Mongolia is in a region that has experienced, during the past century, one of the highest surface warming on our Earth. In terms of climate influences on pastoral systems, during the last 70 years the annual mean air temperature has increased by over 2 °C in Mongolia (Batima et al. 2005; Dagvadorj et al. 2009) and this warming has intensified during the last two decades. Winter temperature has increased by 3.6 °C and spring and autumn seasonal temperatures by 1.5 °C. However, the summer temperature has decreased by 0.3 °C during the past 70 years. Changes in warming are not spatially uniform; winter warming is more pronounced in the high mountains and mountain valleys and less in the Gobi desert and the steppe. Annual precipitation has not changed much, but seasonal patterns of rainfall have changed with the spring season becoming drier, causing decreased plant biomass production and later plant onset in some parts of Mongolia. Frequency of zud (drought in summer followed by cold snowy winter) has increased. Regional warming is also reducing surface water, lowering underground water levels, and decreasing snow covered days with consequences of black zud (winter drought conditions).

In addition, socio-economic and climate conditions of the past 50 years are affecting these systems in dramatic ways. Throughout Mongolia, large changes in environmental, demographic, political, and economic driving forces during the past half century have affected pastoral systems. Since the period of intensive Soviet influence following WWII to the present, the general trend has been toward a greater intensification of resource exploitation at the expense of traditional patterns of extensive range utilization. These socio-economic factors are overriding the effects of any changes in climate statistics on pastoral productivity during the past 20 years of social transition. Thus, climate–land use interactions are being modified by these market and policy changes, which is contributing to the overexploitation of forage production, water availability, and other ecosystem services. Since 1990, political changes and opening of markets have led to modifications in pastoral management due to relaxation of central government controls, privatization of livestock, and access to ‘free-enterprise’ and open market systems. This shift to a free-market economy has led to changes in the livestock sector such as more intensive stocking rates in localized areas, especially around water facilities and villages, and change in animal breeds used. In addition, a more sedentary grazing system has emerged due to the lack of government support for long distance movements of animals and restricted boundaries associated with grazing permission in the current village level grazing systems. These land use changes and greater vulnerability of the pastoral systems associated with livestock losses, increased stagnation of grazing enterprises in rural civic centers, and observations of rising unemployment have led to increased poverty among households and related decline in social services in these civic centers. Although livestock was privatized in rural areas and the number of livestock increased, the livestock industry has suffered due to degradation of pasture and unfavorable climate conditions in recent years (MNE 2001, 2006; MHDR 2011)(e.g., severe weather conditions in 1999–2002 and in winter of 2009–10). As a result, livestock, the source of income for livelihoods of rural citizens, shrank in size and poverty has increased, in general.

Response of pastoral systems to political and economic changes, associated with incentives to sell cashmere, has led to a tripling of goat numbers and a reduction in cattle numbers across Mongolia. This has resulted in both socio-economic and ecological consequences. These changes in pastoral management coupled with climate have increased the degradation of grassland resources. Thus, we expect climate–land use and cover relationships to be crucially modified by the socio-economic forces mentioned above. Nevertheless, the complex relationship between climate variability and pastoral exploitation patterns still form the social–ecological framework for overall patterns of land use.

A key factor in this modification is the continued decline in the number of water points from year to year. Nomadic pastoral seasonal grazing patterns have been disrupted with the loss of these watering points. The increased grazing pressure around the remaining water points has resulted in overgrazing of pastures. In addition to these grazing effects, a warmer and drier climate has created conditions promoting grassland degradation. The forage availability, determined by remote sensing data from 1982 to 2002 in the central parts of Mongolia was affected by these climate effects (Ojima et al. 2004). Ellis and others (2002) showed that the steppe area adjacent to the Gobi region is especially vulnerable to climate and with increased grazing pressures during the past decade have led to desertification. Riparian ecosystems appear to have keystone value in coupled pastoral social–ecological systems. The collapse of these critical ecosystems’ ability to provide water would greatly impact the pastoral community, as water is the most valuable resource for both people and animals in drylands.

Cultural patterns of livestock movement have changed during the past two decades that has increased the vulnerability of these pastoral communities to climate. Environmental degradation has markedly increased in Mongolia and is associated with increased livestock numbers and reduced mobility of herders. Accompanying these trends is a decline in social services available in these villages. Numerous small administrative units or villages became less viable due to a lack of economic and resource support from the central government. Acceleration in desertification has occurred in part because of human influences and in part from changes in the grassland climate. As the number of livestock exceeded pasture carrying capacity, a number of impacts have been observed. These include pastureland degradation, plant production decline, occurrence of ecosystem breakdown, loss of watering holes, and a shift of grasslands to more desertlike conditions. In some areas, soil deteriorated and sand migration increased as bushes and trees, which are the main factor for arresting sand migration, were cut for local use.

4.13.5 Coping Strategies

Ironically, the extent of rangeland vulnerability today in Mongolia is far greater since the transition from a centralized to a market economy. Land degradation due to overgrazing has intensified near cities, areas of concentrated infrastructure, and water resources since the early 1990s. Traditional land-use strategies operated across larger spatial scales (cultural landscape) are in danger of being lost without access to larger cultural landscape elements that allow for seasonal grazing. A reduction in the spatial scale of the cultural landscape has led to reduced resilience and increased vulnerability of the coupled human/environmental systems.

A key to reducing this vulnerability is to enhance the resilience of communities (Walker and Salt 2006). Interestingly, cooperatives based on traditional pastoral networks are reemerging in Mongolia in response to the drought and extreme winter conditions of 1999–2002. The comparative study of pastoral communities shows that a pastoral community with cooperative structures based on traditional networks has lost less livestock compared with other communities during the recent climate disaster (Chuluun and Enkh-Amgalan 2003). Today, the Mongolian rangelands are at the bifurcation stage between two pathways: predominantly private land ownership or traditional land-use culture operated by pastoral communities. It appears that enhancement of pastoral communities based on traditional resilient pastoral networks will lead to a reduction in the future vulnerability of Mongolian pastoral systems.

Finally, the development of the modern cultural landscape of the Mongolian rangelands includes the strengthening of pastoral traditional networks with the introduction of modern technologies such as wireless communication, renewable energy resources, access to appropriate livestock breeding, use of veterinary practices, and access to markets of more finished products. Further development of early-warning systems will reduce vulnerability to extreme climate events through the incorporation of integrated technologies such as remote sensing and modeling to provide improved assessments and forecasting capabilities. There is a good probability of success if such innovative approaches to sustainable development of these natural–cultural landscapes can be implemented and lead to conservation of the critical natural–cultural landscapes of the region.

4.13.6 East Africa Example

Eastern African grassland systems provide an additional view of social–ecological vulnerability due to changes in policies, socioeconomic factors, land access, and climate (Galvin 2009; Galvin et al., 2009). Traditionally, pastoral land-use systems in Eastern Africa have adapted to rainfall variability across grassland landscapes in the region for perhaps thousands of years (Pratt and Gwynne, 1977). Wildlife and pastoral movements have made seasonal treks over vast distances to reduce risk and to take advantage of the elevation and spatial heterogeneity of forage production and availability of water resources. These movements reduce risk by reducing exposure to climate risks, enhance access to food and water resources, and access resource heterogeneity in space and timing of availability (Reid et al. 2008, 2009; Western et al. 2009; Robinson and Berkes 2010). Policy changes have restricted the movement of many pastoralists and the result has been enhanced degradation of these resources and increased vulnerability to climate (Homewood et al. 2009).

East African pastoral systems take advantage of the rainfall heterogeneity that characterizes the East African climate (Ellis and Swift 1988; Ellis and Galvin 1994). Pastoralist and wildlife movement patterns are associated with regional resource availability during the wet and dry seasons. Recent trends in land fragmentation associated with privatization and more sedentary pastoral practices in the region contribute to restricting these pastoral movement practices traditionally employed in the past (Reid et al. 2008). These recent trends of land tenure, use, and protection are leading to increased vulnerability of these pastoral communities and the natural resource base these traditional systems have evolved to respond to (Galvin 2008; Galvin et al. 2008; BurnSilver et al. 2008; Western et al. 2009).

In the Ngorogoro Conservation Area (NCA), restriction of the pastoralists's movement onto the Serengeti Plains due to conservation policies has led to reduced access to forage in the dry season. This reduced movement has increased the degradation of grassland resources in the area and has affected access not only to food resources but also to critical water resources (Galvin et al. 2008). In addition, prolonged stay in the highlands has resulted in the increased exposure to tickborne diseases and other pests reducing the health and productivity of livestock. Conservation policies have also resulted in increased competition between wildlife and livestock and tourism for water. Massive cultivation at the edges of the NCA has led to potential impacts on wildlife corridors (Boone et al. 2008).

Livelihood strategies are also being affected throughout east Africa, with more pastoralists transitioning to farming and converting grasslands to cropland or mixed livestock-cropping systems (Little et al. 2001). Increased reliance on farming in areas of extreme weather variability coupled with a decreasing livestock to human ratio is resulting in degrading social–ecological conditions.

The vulnerability of grassland has been characterized by a number of recent analyses in the region (Galvin et al. 2008; BurnSilver et al. 2008; Robinson and Berkes 2010), and these studies identify a set of factors exacerbating the situation. These factors include (a) greater population density, (b) overuse of surface water resources, (c) intercommunity conflicts, (d) expansion of unpalatable grasses, and (e) policies restricting access to grazing lands (Galvin et al. 2008; BurnSilver et al. 2008). Past strategies for coping with stresses resulting from these pressures are no longer viable, and the continued grazing pressures due to restrictions in mobility are resulting in greater loss of grassland productivity and increased poverty among the pastoralist communities. The interaction among these factors can also lead to cascading effects, further contributing to poverty among the pastoral communities, and increased degradation of natural resources. For instance, drought-induced losses of livestock, especially loadbearing animals such as camels, have resulted in reduced movement of pastoralists in northern Kenya and more reliance on pasture near watering holes (Robinson and Berkes 2010). Camels are used to carrying water to distant landscapes that have available forage, and the loss of this transport mechanism necessitates that livestock need to be closer to water supply points despite having less favorable forage availability. This overusage of forage and water resources leads to further degradation of these natural resources and contributes to increased poverty of these pastoral communities. The inability to utilize these movement strategies due to land privatization and land-use changes has resulted in social changes among pastoralists (BurnSilver et al., 2008; Western et al. 2009). The increased level of poverty and social breakdown of these pastoral communities has led to a condition where there are less community members able to provide relief to other members of the community.

4.13.7 Monitoring and Assessment Strategies for Grassland Ecosystems

There are a number of indicators of grasslands under stress as well as methods to characterize a system that has undergone biophysical changes related to climate and land-use impacts (Herrick et al. 2010; Buenemann et al. 2010). These indicators reflect changes in biological factors (e.g., species composition, change in production patterns), physical structure (e.g., woody encroachment, soil moisture changes), biogeochemical processes (e.g., nitrogen fixation, N emissions), biophysical fluxes (e.g., dust events, evapo-transpiration rates), disturbance regimes (e.g., fire frequency, grazing dynamics), and social losses (e.g., collapse of pastoral productivity, livestock production). Forecasting technologies have advanced, which incorporate field studies, social–economic surveys, remote sensing, and modeling systems to provide the effects of changes on ecosystem productivity and well-being (Boone et al. 2011; Thornton et al. 2006, 2007; Galvin et al. 2009). These systems have been deployed in regions in Africa and Asia.

Our understanding of land-use decision-making processes provides a foundation for evaluating the interactions between factors influencing human activities and their effects on ecosystem services. The environmental context of the system can be determined by the state of ecosystem services and the reliance of the decision maker on these services. Instability in the system may arise when unforeseen loss of an ecosystem service occurs, such as soil stability during a drought resulting in a massive dust storm or lack of water flow leading to desertification or drying of water bodies. The effect on the coupled human–environment system may rapidly appear, although the underlying changes have been occurring over time, undetected until a critical threshold has been met.

Research efforts have recently brought greater attention not only to the role ecosystem services have on the provisioning of key economic goods, but also in the services that sustain, regulate, and support life on Earth (Costanza et al. 1997; Daily 1997; Daily and Ellison 2002). Grassland social–ecological systems provide a wide array of goods and services upon which pastoral well-being, even survival, depends. Whereas consumptive goods provided by land systems, such as forage, grains, animal protein, and fiber and wood products, are typically valued through well-developed markets, the contributions to society and ecosystem functioning of the 'underpinning' services provided by ecosystems often remain 'invisible' and unvalued (or undervalued) and the linkage to social dynamics are rarely considered. The array of such services is broad, from those services that regulate critical human–environment processes (e.g., climate, disease, flooding, detoxification) to services that support economic activity (e.g., soil formation, primary productivity, nutrient cycling, pest control, pollination).

Understanding effects of use of land resources is dependent on being able to better incorporate ecosystem services into the decision-making process. In addition, evaluation of changes in the state of ecosystem services (i.e., maintaining soil fertility, supplying water resources, and food and fiber production) will be important to the development of the appropriate coping or adaptive strategies under different human–environment stresses. The case studies described above provide an illustration of the interactive role that social, biological, and physical components of coupled human–environment systems play. These case studies enable us to better understand the interactions of the social–ecological factors determining the vulnerability or resilience of these systems to different scenarios of social and environmental conditions.

Characterizing and determining these ecological thresholds are challenging to resource managers and to pastoral decision makers due to the sudden and often irreversible nature of these changes in ecosystem services and the novel states that emerge (Hobbs et al. 2006). Some examples of changes in the social–ecological systems due to climate and management changes from our case studies include:

- Declining water availability, local overgrazing, reduced well-being of livestock and pastoralists
- Sedentary land-use practices leading to lack of access to water and forage resources, resulting in overuse of resources and change in land-use systems
- Market pressures and demographic patterns leading to loss of pastoral livelihoods

Socio-ecological thresholds due to environmental and socio-economic drivers are being triggered in many grassland systems around the globe. Many of the basic understanding of where and when a threshold will be crossed is still unclear (Julius et al. 2008). However, the inherent sensitivity of the grassland system to climate variability and to various land-use changes has been documented (Ojima et al. 1993; Parton et al. 1994; Archer et al. 2001; Reynolds et al. 2007). The fragmentation of landscapes and the discontinuity of landscape processes also contribute to ecosystem and biodiversity vulnerability in ways that contribute to triggering social–ecological thresholds (Ojima and Corell 2009; Chuluun et al. 2008; Galvin et al. 2008).

Assessing social–ecological vulnerabilities can be conducted using various approaches (Adger and Kelly 2001; Adger et al. 2011; Moss et al., 2000). These approaches provide a framework to better correlate social outcomes, such as poverty reduction, against measures of capital assets or other measure of available resources. Other approaches take measure of societal needs, such as food availability, water access, health care, schools, and other services, which are evaluated relative to various factors such as commodity price volatility or climate variability. These approaches call for better integration of environmental and societal metrics to evaluate social–ecological vulnerability. The choices of coping strategies are determined by the capital resource assets (i.e., natural, human, social, financial, and built capital) available to different community members in a particular location and stage of societal development. Decisions are based on multiple criteria related to various cultural and economic goals for various communities (Tschakert et al. 2007). Regional decisions to cope with stress and to overcome vulnerable conditions will reduce the impacts of these stresses and make decisions that will benefit some and differentially affect others.

Monitoring of key climate characteristics related to temperature maxima or minima, seasonality of precipitation patterns, and interactions among climate characteristics will provide greater forewarning of impending critical thresholds in currently unaffected ecosystems. A number of ecosystem services can also be monitored to assess the impacts of change to society.

Critical to knowledge about ecological thresholds is a prognostic capability to better utilize, in an integrative fashion, a suite of observations in a way that a social–ecological forecast can estimate the probability of a threshold being crossed in one or more system processes (Walker and Meyers 2004; Hobbs et al. 2006; Lyytimäki and Hildén 2007).

Complex multidimensionality of ecological thresholds can be resolved through the use of integrative modeling and analytical approaches (Boone et al. 2011; Thornton et al. 2006; Reynolds et al. 2001). Development of a threshold prognostic or ecological forecasting tool to evaluate probabilities of achieving a threshold event would be extremely helpful in managing natural resources and developing adaptive management strategies to maintain ecosystem services.

4.13.8 Opportunities and Challenges for Managing for Change in Grassland Systems

Grassland ecosystems are being affected by multiple stresses and these effects are impacting society, biological communities, and ecosystem services in novel ways (Hobbs et al. 2006). As illustrated in the case studies presented here, unintended consequences arise from policy or market changes affecting pastoral decision making without considering concurrent environmental trends, such as any changes in grassland climate. Some of these impacts may only have temporary disruptions, but in some cases, such as conversion of grasslands to croplands, loss of water supplies, or changing livestock mixtures, have pushed these systems toward critical thresholds. Such system dynamics are indicative of complex adaptive systems and therefore are not easily managed to meet the multiple-state characteristics of human–environmental systems. An optimal management approach may, in fact, be counterproductive to development of a more robust adaptive management approach that recognizes the existence of multiple states and the importance of change as a basic component of the system dynamic (Berkes and Folke 1998; Gunderson and Holling 2002; Walker and Meyers 2004; Tschakert et al. 2007). Hence, an integrated decision-making framework for adaptive management scaled to the issues confronting managers and decision makers is needed. A critical aspect of the information needed is the scale of climate information necessary to make decision of plausible changes to resources.

Management options to reduce vulnerability of grasslands to climate and other social–ecological changes affecting grassland ecosystems need to incorporate research and management perspectives to deal with the dynamic nature of change they experience (Joyce 2009; Robinson and Berkes 2010; Sietz et al. 2011; Adger et al. 2011). The feasibility of these management actions will depend on the adaptive capacity of the social–ecological system and the linkages between natural resources, ecosystem services, and social–economic conditions (Joyce 2009; Adger et al. 2011). The framing of management actions need to clarify metrics and goals for management in ways that can better identify thresholds that would impact the grassland ecosystem (Adger et al. 2011).

Approaches suggested include the involvement of stakeholders at multiple scales in order to address multiple scales of changes in the social–ecological system, develop a coordinated way of implementing policy and management decisions affecting livelihoods and ecosystem services of the grassland ecosystem, and implementing adaptive management practices and monitoring schemes that are responsive to temporal and spatial dynamics of the grassland resources and pastoral communities (Joyce 2009; Robinson and Berkes 2010; Adger et al. 2011). This integrative approach will facilitate the incorporation of uncertainty and risk assessments, link modeling analysis and decision making at appropriate spatial and temporal scales, and provide a mechanism for sharing resources and knowledge across affected communities and planners (Joyce 2009).

A number of key elements are used, including identifying specific concerns of the community and for issues the community faces within the prescribed socio-environmental context. Scale of analysis in space and time can be set at an appropriate level with assistance of the stakeholder community (e.g., multiple public and private decision makers and managers and information brokers). Often, time scale needs to be matched to various issues that respond at different scales, such as rainfall at certain times of the year, heat waves at critical times of plant development or livestock production, or other climate triggers that affect maintenance of infrastructure or affect delivery of ecosystem services. Identifying the critical time scales of decision making becomes an important component of the adaptation strategy framework to ensure that appropriate climate and other information are provided. Development of the appropriate scenario information from different climate projections that are more aligned to the critical management or decision-making issue to the given situation is a fundamental consideration. The final step is to design a multidecadal strategy to deal with possible changes in climate and its effects on the socio-environmental system. This course of planning is thought to be recursive in nature. That is to say, it should be revisited every few years or so. Incorporated into this framework is the need to frequently update information regarding changes in the system.

4.13.9 Summary

Grasslands exist in regions with variable precipitation and due to moisture and temperature limitations may not provide suitable conditions to maintain cropping systems on a regular basis. These ecosystems continue to nurture a large diversity and number of ungulates, which are valued for their vast quantity and the role these animals play in maintaining these ecosystems. Humans have thrived in these environments depending on the ecosystem services for food, energy, and shelter for many thousands of years. Despite environmental variability, land-use systems have been devised to accommodate these vagaries in moisture availability. However, as we view these systems today across the globe, we see social–ecological systems that are increasingly vulnerable due to increased stress, human pressures, and climate changes.

In these grassland systems, traditional land-use systems have taken advantage of the variability in space and temporal availability of ecosystem services by developing nomadic utilization wildlife, livestock, water resources, and forage. Increased human pressures coupled with policies restricting movement of people and animal resources have led to more sedentary livestock production. The sedentarization of land use in these systems has resulted in overexploitation of accessible grassland ecosystem services. This has led to increased degradation of these ecosystems, through overgrazing, draining of shallow aquifers, and loss of biodiversity. The combined effect of these changes has led to increased vulnerability of the social–ecological systems that have emerged. The set of social–ecological examples provided here for North America, Mongolia, and East Africa demonstrate the growing vulnerability of these systems under increased human pressures, inappropriate responses to market forces, increased variability and changing seasonality of the climate system, and the restriction of movement to better accommodate environmental variability.

Adaptation strategies to deal with these enhanced vulnerabilities across these different regions will necessarily take on different pathways due to their local social–ecological conditions and the current adaptive capacity of the system under evaluation. However, there are various principles that have emerged to develop place-based strategies. These include participatory methods to codevelop goals and means to meet these goals, framing strategies within a multicriteria framework, appropriately evaluate and utilize capital resource assets to enhance resilience where possible or to assist in making adaption actions work, and last, to manage for change.

Glossary

Asset Any item of value that potentially is exposed to hazards; can include buildings, other infrastructure, human beings, ecosystems, etc.

Coastal zone The potentially wide area between the dry land above the littoral and the shelf margin.

Hazard A potentially harmful event.

Local sea-level The vertical distance between the sea surface and land surface.

Global sea-level The global average of local sea-level.

Resilience The ability of a system to absorb disturbance while retaining its basic function and structure.

Risk The probability that a hazardous event will cause a certain damage to an asset.

Vulnerability Characteristic of an asset to experience damage if exposed to a hazard.

4.14.1 Introduction

Coastal ecosystems provide important environmental, social, and economic service functions. Coastal habitat and ecosystems are generally some of the richest areas for biodiversity. These systems are adapted to the various compartments that typically occur in the wide coastal zone between the hinterland and the shelf margin. Coastal wetlands include marshes, swamps, and other plant communities that are flooded part of the time, and that are hydraulically connected to the sea. Located at the interface between land and sea, tidal marshes provide unique ecosystem services for waste treatment, biological productivity, and regulation of disturbances.

Small changes in Local Sea Level (LSL) can lead to significant changes in some of these compartments posing extreme challenges to the ecosystems, particularly if these changes take place rapidly. LSL changes depend on both changes in sea surface height and land surface height. Tectonic uplift and land uplift due to postglacial rebound reduce local sea-level rise (LSLR), while local subsidence will accelerate it. In combination with changing weather extremes, changes in LSL could modify the pattern of coastal inundation with severe impacts on sensitive coastal ecosystems. The process of inundation leads to both the conversion of dry land to wetland and the conversion of wetlands to open water, thus destroying coastal habitats or forcing the ecosystems to migrate inland. However, coastal protection often inhibits migration, and a loss of valuable ecosystems would be inevitable.

Local sea-level rise would also increase the destructive force of coastal storms, leading to increased coastal erosion and an acceleration of ecosystem losses. Increased erosion would likely amplify the effects of LSLR. As a consequence, the total shoreline retreat could be much larger than suggested by present-day topography. Globally, the combined effect of LSLR and erosion could be devastating. For example, an average LSLR of 1 m along the coasts of Bangladesh would inundate 17% of the country (Titus 1990), 20% of the farmland in Egypt is below 2 m of current sea-level, and many other coastal areas would face large erosion (Figure 1). Any LSLR would also shift the tidal zone and areas inundated during storm surges further inland, with the speed of this shift depending on the local topography and the speed of the LSLR.

The vulnerability of coastal wetlands to LSLR depends on many factors, such as the coastal topography, the tidal range, and human interferences such as coastal protections and development. Depending on these factors, coastal wetlands may compensate for LSLR by vertical or horizontal migration, if the speed of change does not exceed the capability of the

Figure 1 Coastal areas in Asia that are at risk of inundation. The color code of the map indicates elevation above current sea level. Most areas below 2 or 3 m are at risk of inundation from storm surges, and the probability of inundation and erosion during storm surges will increase dramatically if LSL rise in these location. Areas below 1 m are likely to be permanently inundated if LSL rise by 1 m at these locations. Graphics produced with the tool available at http://www.globalwarmingart.com/wiki/Special:SeaLevel.

ecosystems to migrate. In general, a rise of LSL leads to a reduction of terrestrial influence and an increase of marine influence. However, the changes depend strongly on coastal topography and do not linearly increase with the LSL change (Craft et al. 2009). In areas with large tidal ranges of 2 m or more, tidal marshes are less susceptible to LSLR than in areas with small tidal variations. If sediment supply allows tidal marshes to migrate vertically, then LSLR can be compensated to some extent. In some coastal areas, an LSLR would result in submergence and significant reductions of tidal marshes, while in other areas, salt marshes may transgress landward and in this process replace tidal freshwater and brackish marshes. A possible decline in the area of tidal marshes area and the conversion of habitats would impact the delivery of ecosystem services provided by coastal wetlands.

Coastal zones are attractive to humans for a variety of reasons. Besides a significant migration trend in human population from rural to urban areas, a migration into the coastal zone is taking place, increasing the pressure on coastal environments. During the last several decades, human interaction has reduced coastal wetlands globally by more than 30%, and more than 35% of the mangroves have been lost during the last 20 years (Gilman et al. 2006a). Any LSLR will add stress on top of this on-going human alteration of the coastal zones. In many areas, coastal protection in response to LSLR will further acerbate the stress.

Regional changes in weather patterns, melting of ice sheets, and increases in ocean heat could lead to significant global sea-level rise (GSLR), and assessments of the potential impact indicate possible extreme costs particularly for urban coasts (see Plag and Jules-Plag 2012). Very few assessments have focused on the economic impact of sea-level rise associated with ecosystem loss through inundation, erosion, and other sea-level related processes. Examples of a few exceptions are studies of potential sea-level rise impacts on the Everglades in Florida (Madden and Goodin 2007), on the vast coastal area and flood plain zone in Bangladesh (Sarwar 2005), and on mangroves (Gilman et al. 2006a,b). The development of policies for adaptation and mitigation of sea-level rise related impacts is also mainly focused on urban coastal areas. As a consequence, coastal ecosystems would likely be in a triple-loss situation: human alterations are leading to degradations and loss; sea-level rise would increase stress and require ecosystem migration; the human response to sea-level rise would increase coastal alterations and add stress.

IPCC prediction of the 21st GSLR displays a large range ranging from a few centimeters to 1 m, but many climate change assessments conclude that Global Sea Level (GSL) will only rise on the order of 0.5 m by the end of the twenty-first century (e.g., Bindoff et al. 2007), although it is often stated that larger values cannot be excluded (e.g., Church et al. 2010). However, studies of paleo-records indicate that there is no scientific basis to exclude GSL changes of 2 m or more within several decades. This renders model predictions unsuited as a basis for the planning of adaptation. Taking into account that LSLR can deviate more than ±100% from the global average, this implies that changes of several meters within a few decades are within the possible range of LSLR. Superposing this potential LSLR over the low-lying coastal areas shown in Figure 1 for Asia indicates the scale of the inundation and erosion problem. The situation in other coastal areas is similar to the one shown for Asia.

A key consequence of sea-level rise is the loss or degradation of wetlands in the coastal zone. There are, however, two compensating processes that might offset this potential threat: (1) an LSLR would inundate and flood areas that are now dry land, and thus, create new wetlands; (2) wetlands can grow vertically by accumulating sediment and organic material. The potential of these processes to slow down or prevent a major loss of wetlands as a consequence of LSLR may be limited due to two factors: (1) in many cases, land just inland of wetlands has been developed, and moving people and infrastructure to make room for the creation of new wetlands may not be acceptable socially and economically; (2) the rate of 21st LSLR could exceed the rates experienced during the last four to six thousand years, and while wetland ecosystems may have been able to keep pace with the past rise, they may not be capable of coping with a much accelerated rise.

In order to understand the potential impact of LSLR and the associated changes in the compartments of the coastal zone on ecosystems and their services, we need to characterize the different compartments, identify their services, and assess their resilience to spatio-temporal variations in these compartments. The coastal zone is an incredibly complex and diverse environment, which defies easy organization into neat compartments. Even a clear definition of the coastal zone is not available. Coastal ecosystems display a wide range of geological features, dynamic conditions, climate conditions, and species. Nevertheless, for an understanding of the vulnerability of coastal ecosystems to LSLR and inundation changes, as well as, their susceptibility to human activities to protect the coasts and reduce the impact of flooding, a classification is required. Here we will focus on those coastal and marine compartments most sensitive to changes in LSL.

For the marine environment, we follow Madden and Goodin (2007), who identify five main regions from the supratidal zone on the landward endpoint to the central ocean: the estuarine, freshwater-influenced marine, nearshore marine, neritic, and oceanic regimes (see Table 2 in Section 4.14.4). In addition, we also need to consider the land above the supratidal zone, which may be inundated, converted into wetlands, and eroded due to LSLR, depending on the current topography, the energy environment, and the geology.

In the following, we will first clarify our risk-based approach to the mitigation of impacts of LSL changes on coastal flooding and ecosystems. We will then discuss plausible changes in LSL and GSL and provide a typology of the sea-level hazards in the coastal zone including coastal protection (see Section 4.14.3). In Section 4.14.4, we will review the coastal ecosystems with emphasis on their service functions, and in Section 4.14.5 discuss the vulnerability of these systems to LSLR and coastal protection. Section 4.14.6 summarizes the sea-level related risk for coastal ecosystems, and in Section 4.14.7, we will discuss strategies and policies that might limit future loss of coastal wetlands.

4.14.2 A Risk-Based Approach to Mitigation and Adaptation

Changes in mean LSL and short-term temporal variations (such as waves, tides, storm surges) of LSL can significantly change the energy environment of a coastal area and lead to coastal erosion and inundation. Inland hazards caused by LSL rise include inundation, saltwater intrusion, increased erosion, and higher storm surges. As a result of LSL rise, the Probability Density Function (PDF) of these sea-level related hazards can change significantly. Any risk-based planning of mitigation and adaptation has to account for this.

Any decision on mitigation and adaptation needs to take into account the probability of the hazard actually occurring, and the ability of a system, be it a human socio economic system or an ecosystem, to cope with the hazard. The study of the vulnerability of human and natural systems to hazards is a relatively new interdisciplinary field, which is developing particularly with a view on climate effects, and other natural hazards. A common language has not been developed yet and experts from different field put different meanings to the terms used (e.g., Dolan and Walker 2003). In particular, approaches differ between natural and social sciences (e.g., Brooks 2003).

Here we take a risk-based approach that is commonly used for natural hazards and particularly geohazards. For a given hazard h, a given recurrence time interval T, and for a prescribed intensity I, the associated risk $r(I)$ expressed in currency is given by

$$r_h^T(I,x,t) = p_h^T(I,t)\cdot V_h^{a(x,t)}(I,t)\cdot a(x,t) \qquad [1]$$

where x is the location, t time, p the hazard giving the probability that the hazard with intensity I will occur in the considered recurrence interval, V the vulnerability of an asset a for hazard h at intensity I, and a being the asset exposed at location x. To assess the total risk R associated with a hazard, we can use

$$R_h^T(x,t) = \int_0^{I_{\max}} r_h^T(I,x,t)\mathrm{d}i. \qquad [2]$$

Equations [1] and [2] provide a basis for risk management and the prioritizing of mitigation, adaptation, and monitoring. The risk is strongly dependent on the chosen recurrence time interval. Selecting a short time interval may seriously underestimate the risk, while a very long interval may lead to unrealistically high risks.

Assets can be any system from a single building, a transportation infrastructure, a city, a socio economic system, to an ecosystem or a natural resource such as groundwater. We use the term vulnerability to indicate the damage a hazard would cause to an asset, if the asset was exposed to the hazard. This is the approach taken mostly in disaster risk research for natural hazards. Climate scientists tend to consider vulnerability in terms of the likelihood of impacts of weather and climate related events (Nicholls et al. 1999) or the damage inflicted by changes in climate statistics (outcome vulnerability (e.g., Kelly and Adger 2000; Pielke Sr. et al. 2012)), while social scientists often consider vulnerability as the set of socio economic factors determining the ability of a social system to cope with stress or change (contextual vulnerability) (Allen 2003). In our definition, vulnerability does not depend of the hazard actually occurring, but is a latent characteristic of the asset. For example, one building may be more vulnerable to fire hazards than another building, independent of the fire actually occurring.

All three factors in eqn [1] depend on time. Both natural and anthropogenic assets at a given location can change and their value can change as well. Vulnerability of the assets also can change over time. In particular, adaptation can reduce vulnerability, while pre-stress can increase it. If we denote the impact of adaptation at time t on vulnerability by $\alpha(t)$, then vulnerability is given by

$$V_h^{a(x,t)}(I,t) = V_h^{a(x,t)}(I,t)\Big|_{t=t_0} - \int_{t_0}^{t} \alpha(t)\mathrm{d}t. \qquad [3]$$

The probability p of a hazard h of intensity I occurring within time interval T also depends on time. Particularly for climate-related hazards, climate change will change p.

For most natural hazards, including most sea-level related hazards, there are limited options to impact p. However, in some cases, land use can significantly change the PDF of a hazard (e.g., for floods, droughts, landslides). Likewise, climate (in particular changes in precipitation and temperature) can modify the PDF significantly. Examples are the increasing melting of permafrost in northern Canada and Alaska, which has led to increased landslides that threaten roads and pipelines. Increased precipitation and periods of more rapid snow melt can change the PDF for floods and droughts (e.g., Solomon et al. 2007), and, importantly, changing intensity, frequency, and path of storms impact the PDFs for storm surges with potentially large spatial variability (e.g., Katsman et al. 2011; Schwerzmann and Mehlorn 2009).

The main measures for risk reductions lie in a reduction of vulnerability and, if possible, the spatial exposure of assets. For coastal ecosystems, mitigation through changes in exposure is of limited value, since coastal ecosystems are adapted to locations and often cannot be relocated. Thus, coastal protection is often the only means to reduce the impact of LSL changes on coastal ecosystems. However, coastal protections also modify many compartments of the coastal zone and thus can have a degrading impact on coastal ecosystems, or even remove the basis for existing ecosystems. It is this trade-off between protection and negative impacts that poses a great challenge to coastal zone management.

Adaptation and mitigation are insurance against the risk. While eqns [1] and [2] provide a basis for a quantitative analysis of the risk, willingness to engage in adaptation and mitigation depends on risk perception. Zahran et al. (2008) studied why cities would voluntarily commit to the Cities for Climate Protection (CCP) campaign and found that those cities that had suffered more from extreme events were more willing to commit. The challenge of LSLR is that it is a slowly developing disaster. We normally do not realize the hazard until it is too late. While there is a growing acceptance of the risk for coastal cities associated with LSLR, the risk for ecosystems, for which the societal value is not obvious, is much less accepted, and costs for adaptation and mitigation are often postponed.

Another term relevant for our discussion is resilience. Resilience can be defined as the ability of a system to absorb disturbance while retaining its basic function and structure (Walker and Salt 2006). Social and ecological resilience are related (Adger 2000). For a social system, resilience is the ability to cope with external and internal stresses as a result of social, political, and environmental change. For an ecological system, resilience is a characteristic of the ecosystems to maintain itself in the face of disturbance. Particularly, for social communities depending on ecological and environmental resources for their livelihoods, there is a clear link between social and ecological resilience. On a global scale, resilience of humanity is linked to the resilience of the global biosphere to human interference, including human climate forcing (National Research Council 2005) coupled with natural climate variations, which are often quite large (Rial et al. 2004; Meko et al. 2007). There are global boundaries the transgression of which may put the global ecosystem into a new state, which could still be acceptable for the ecosystems, but outside of the safe space for humanity (Rockström et al. 2009a,b). Decisions on mitigation of impacts on ecosystems have to account for this link between ecological and social resilience.

4.14.3 The Hazards: Sea-Level Change and Coastal Protections

We define LSL as the height h of the sea surface above the underlying surface of the solid Earth, e.g.,

$$h(\lambda,\theta,t) = \begin{cases} r_1(\lambda,\theta,t) - r_0(\lambda,\theta,t) & : \text{ in the ocean} \\ 0 & : \text{ on land,} \end{cases} \qquad [4]$$

where r_0 and r_1 are the geocentric positions of the sea floor and sea surface, respectively (Plag 2006a). λ and θ are the geographical longitude and latitude, respectively. Variations $\xi(t) = h(t) - h_0$ of LSL are the result of variations in r_0 or r_1 or both. GSL is the average taken over the surface of the oceans. Changes in GSL equal the changes in the Global Ocean Volume (GOV). We note here that in many publications, the term 'sea-level' is not explicitly defined, and often refers to sea surface height observed in a geocentric reference frame (also sometimes falsely referred to as absolute sea-level, Blewitt et al. 2010). LSL defined by eqn [4] often is referred to as relative sea-level, although the distance between sea surface and land surface is an absolute quantity independent of the reference frame.

LSL as defined above is the quantity that is directly related to the potential impact of global and regional changes in climate and sea-level in a given coastal area. At any location, LSL is the result of a number of global, regional, and local-scale Earth system processes altering sea surface height, land surface height, or both (Figure 2). These processes, which act on a wide range of time scales, from a few seconds to millions of years, include mass relocation in ice sheets, glaciers, land water storage, and oceans; deformation of the solid Earth and gravity field changes caused by the mass relocation; changes in ocean heat storage and ocean currents; changes in atmospheric circulation; tectonic processes; and local coastal subsidence caused by natural and anthropogenic processes. These processes lead to large spatial variation in LSL on all time scales, and the relation between changes in GSL and LSL at any given coastal location is rather complex. For example, melting of ice on Greenland would increase GSL, but it would lead to a fall of LSL at the coasts of Greenland and any land mass in the vicinity of Greenland, while the rise in LSL on the Southern hemisphere would be larger than the global average.

No single Earth system model is currently available that can accurately predict past, present, or future LSL changes, and it is unlikely that such a model will become available in the near future. Moreover, underlying processes (including future greenhouse gas and aerosol emissions and land use change Lovejoy and Schertzer (2012); effects on climate of anthropogenic re-engineering of the planet (Syvitski 2012); changes of ice sheets and glaciers; natural low-frequency climate variations National Research Council (2005)) likely will remain unpredictable on century time scales for a long time to come (McMichael et al. 2006; Lipscomb et al. 2009). Thus, quantitative, model-based predictions for twenty-first century LSL with sufficiently narrow uncertainties to be actionable cannot be provided today, and most likely not in the foreseeable future.

Our inability to predict future LSL trajectories within narrow uncertainty bands rules out a deterministic approach to coastal risk assessments and the planning of coastal protection as

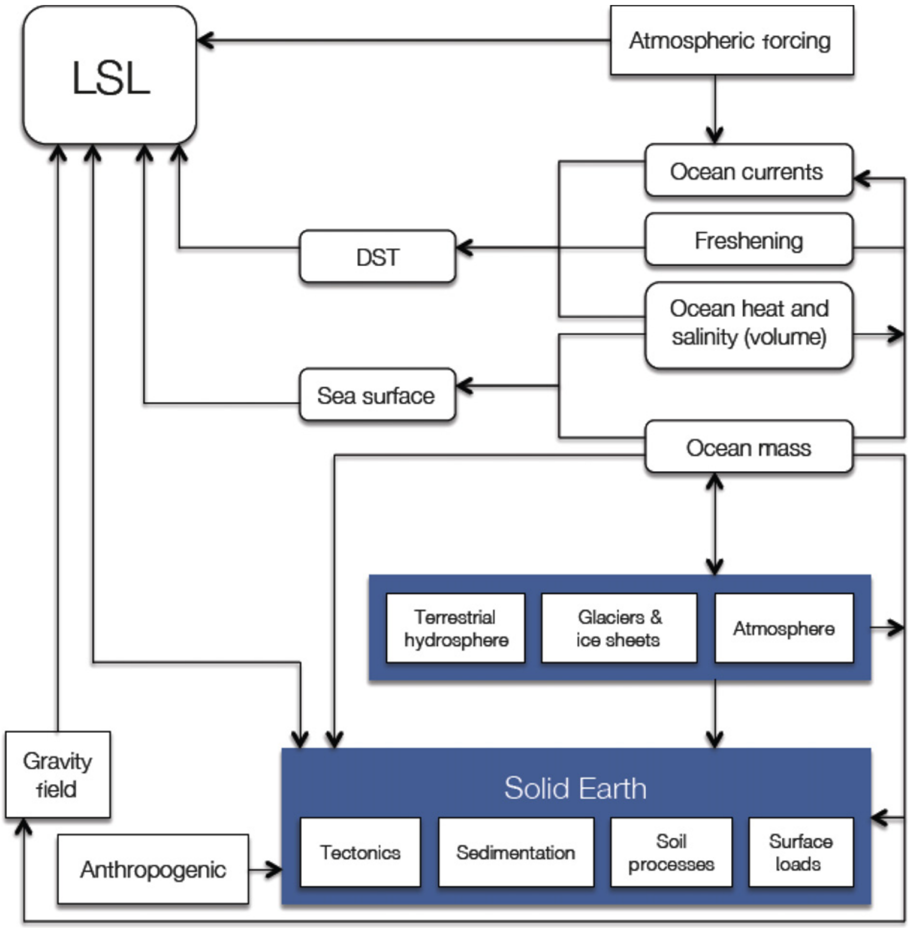

Figure 2 Processes and factors causing long-period LSL changes. Mass movements in the terrestrial hydrosphere (groundwater, rivers, lakes, and reservoirs) and land-based cryosphere (glaciers and ice sheets) and mass exchange with the ocean load and deform the solid Earth and affect the gravity field. The deformations and the associated gravitational changes result in LSL changes, depending on where mass has been relocated. Ocean mass changes as well as ocean volume changes caused by heat and salinity changes affect the sea surface position. Heat and salinity changes also affect the ocean currents and thus change the Dynamic Sea Surface Topography (DST). Freshening caused by melting sea ice contributes to both changes in GOV and DST. Atmospheric circulation forces regional wind-driven currents affecting the DST. DST and sea surface changes caused by regional and global processes change LSL in any location. The atmosphere also acts locally on the sea surface and thus changes sea level. Past changes in the ice sheets and glaciers lead to postglacial rebound, which affects sea level through vertical land motion and geoid changes. Tectonic processes in the solid Earth both result in vertical land motion, changes in the size of the ocean basins, and changes in the geoid. In areas where sedimentation takes place, the compaction of the sediments and their load on the solid Earth introduce vertical land motion. Moreover, changes in LSL feedback on the solid Earth and can cause the destruction of peat through oxidation and thus lead to subsidence. Anthropogenic vertical land motion associated with exploitation of groundwater, oil, and gas as well as changes in sedimentation can change the Earth surface position. Variations in sedimentation due to river regulation (reduction) or land use (increase) also affect LSL, particularly near river deltas. Figure modified from Plag, H.-P., 2006a: Recent relative sea-level trends: an attempt to quantify the forcing factors. *Phil. Trans. Roy. Soc. London, A*, **364,** 1841–1869 and Sahagian, D., et al., 2009: Earth observation: serving the needs of an increasingly global society. *Global Geodetic Observing System: Meeting the Requirements of a Global Society on a Changing Planet in 2020,* H.-P. Plag and M. Pearlman, Eds., Springer Verlag, Berlin, 153–196.

a basis for mitigation of inundation risks. Instead, a statistical approach is needed that takes into account the PDF of decadal to century-scale LSLR. In order to avoid under or over investments, this approach requires a reliable estimate of the PDF of LSLR. In particular, the reliability of the PDF at the high end, e.g., the large rapid rises, is crucial. For sea-level hazards, a rapid large rise is the improbable, high-impact event that is difficult to plan for. It is this event that will cause huge disasters if not anticipated and planned for, and the event that will demand extreme economic efforts to prepare for, which could be wasted if the probability of the event is overestimated.

4.14.3.1 GSLR Discussion: The Deterministic Approach

Much of the discussion on ocean-warming and ice-melt induced sea-level rise has focused on projected GSLR for the twenty-first century. A related question raised in many contributions is to what extent the observed twentieth century GSLR of $\approx 0.2\ \mathrm{mm\ year}^{-1}$ already showed an accelerated rise compared to a presumably far more stable GSL during the last few millenniums (Figure 3, see also Church and White (2006)). Cronin (2011) points out that the notion of a very stable sea-level over the last two millenniums is not supported by

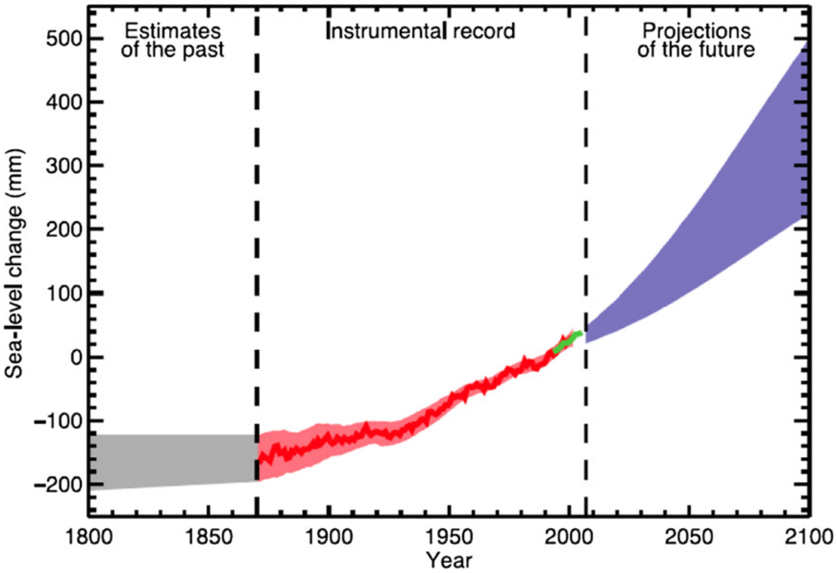

Figure 3 GSL changes between 1800 and 2100. GSLR prior to about 1850 is generally estimated to be on the order of 0 to 2 mm year^{-1}. Since 1850, the rate of GLSR has been on the order of 2 mm year^{-1} with a possibility of larger rates of about 3 mm year^{-1} at the end of the last century (e.g., Cazenave et al. 2010). IPCC projected rates of GSLR for the twenty-first century are between 3 and 5 mm year^{-1}, depending on assumptions of the emission scenario (Bindoff et al. 2007). However, as noted in the text, the models used for these projections do not accurately include all human climate forcings nor are they able to represent low-frequency climate variability and longer-term changes in climate statistics. If, for example, the large ice sheets contribute significantly, then the rates would be much higher. Consequently, the range of plausible GSL trajectories for the twenty-first century is much wider than the figure indicates. Figure from Bindoff, N. L., et al., 2007: Observations: oceanic climate change and sea level. *Climate Change 2007: The Physical Science Basis. Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change*, S. Solomon, D. Qin, M. Manning, Z. Chen, M. Marquis, K. B. Averyt, M. Tignor, and H. L. Miller, Eds., Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA.

observations, particularly if regional deviations from the global mean are taken into account. However, compared to the large fluctuations of GSL and even larger fluctuations of LSL in many locations, during the last million years, GSL has to be considered exceptionally stable over the last few thousand years (**Figure 4**).

Figure 5 summarizes the GSLR projections for the twenty-first century given in the IPCC assessments. The models used for the predictions have been validated against the recorded data from past decades, but the model simulations underestimate the GSLR observed during the twentieth century (see **Figure 5.21** in Bindoff et al. 2007). The large range of IPCC twenty-first century GSL trajectories arises from the range of the projected emission scenarios, as well as, uncertainties in the model response to these scenarios. However, since the models used for the projections do not accurately capture all human and natural climate forcings, the actual range of plausible GSL trajectories is much larger than indicated in **Figure 5**. It is interesting to note that in earlier studies, sea-level rise estimates for the twenty-first century were larger than those predicted by IPCC AR4 (see, e.g., Figures 1–4 in Titus 1988).

Concerning thermal expansion, model simulations of twentieth century heat uptake by the oceans do not fully match the model predictions (Cazenave et al. 2009, 2010), thus putting a question mark on the validity of the projections for this contribution. Observations of the retreat of glaciers and ice caps exclusive of Greenland and Antarctica (GIC) have been, in a number of situations, more rapid than models have simulated (e.g., Meier et al. 2007). The uncertainty in the projections of surface climate, where glaciers and ice sheets exist, adds to the uncertainty of the modeling of GIC response to temperature and environmental changes.

Most importantly, uncertainties related to the potential contribution of the Greenland Ice Sheet (GIS) and Antarctic Ice Sheet (AIS) make it very difficult to constrain the upper limit of the 21st GSLR. Particularly, the AR4 emphasizes the large uncertainty in the upper limit arising from an unknown potential contribution of the large ice sheets. This has lead to a significant debate within the scientific community about the quality of the IPCC GSLR projections for the twenty-first century. A strong focus has been on the potential contribution of the large ice sheets due to potential dynamic processes that may occur if the ice sheets warm (e.g., Pfeffer et al. 2008; Holland et al. 2008; Bamber et al. 2009; Jiang et al. 2010). Potential dynamic effects include very rapid movements of ice streams, leading to potential GSLR exceeding 10 mm year^{-1}, a contribution far larger than any of the other terms. The possibility of a collapse of parts of the ice sheets cannot be excluded (e.g., Vaughan et al. 2007), especially if there would be rapid loss of surrounding ice shelves that could increase the ice stream flows (e.g., Rignot et al. 2008a). The physics of these processes are not well understood and, hence, these processes are not accounted for in the models. However, omitting what likely will be the most important contributor to GSLR must raise a red flag: the IPCC projections of 21st GSLR and beyond may be significantly too low. It is important to emphasize, however, that since our understanding of the climate system is incomplete; other changes in global sea-level rise (including a leveling off or even a fall) are certainly possible. This could

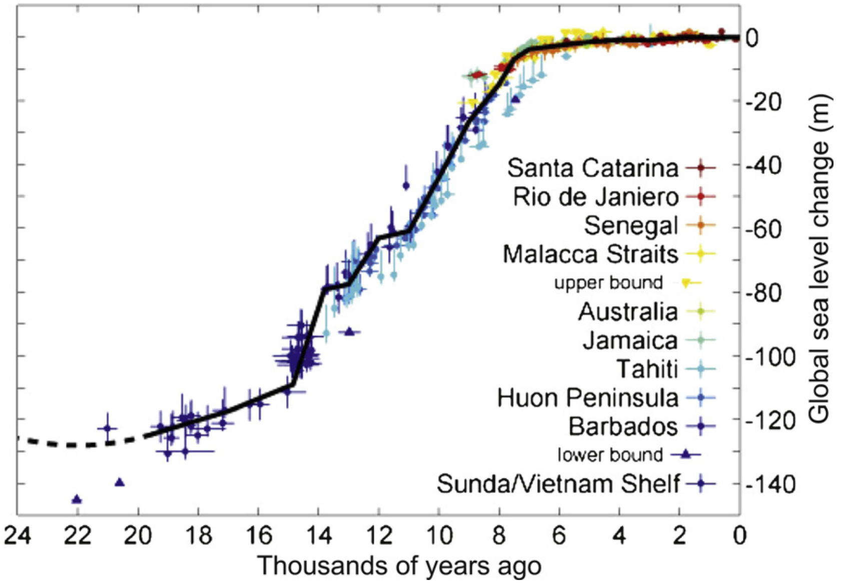

Figure 4 GSL during the last 24 000 years. Data from Fleming, K., P. Johnston, D. Zwartz, Y. Yokoyama, K. Lambeck, and J. Chappell, 1998: Refining the eustatic sea-level curve since the last glacial maximum using far- and intermediate-field sites, *Earth Planet Sci. Bassett, 2005: Modelling holocene relative sea-level observations from the Caribbean and South America. *Quat. Sci. Rev.*, **24** (10–11), 1183–1202, http://dx.doi.org/10.1016/j.quascirev.2004.10.005. Modified from the figure available at http://en.wikipedia.org/wiki/File:Post-Glacial_Sea_Level.png.

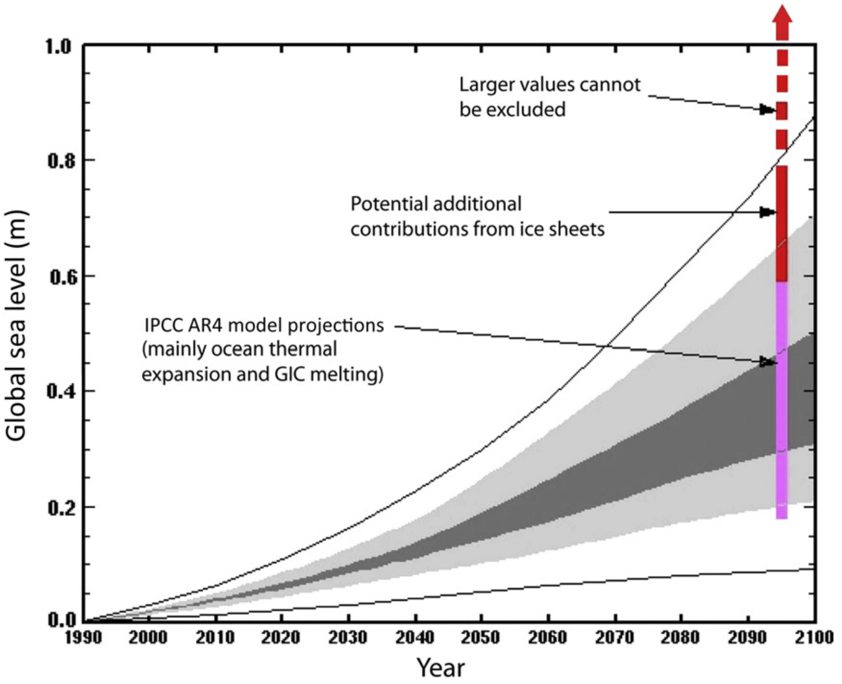

Figure 5 Summary of projected GSLR for the twenty-first century: The lines and shading indicate the IPCC 2001 projections for the period 1990–2100 (Church et al. 2001), with the central dark shading being an average of models for the range of SRES greenhouse gas emission scenarios. The light shading is the range for all models and all SRES scenarios and the outer bold lines include an allowance for land-ice uncertainty. The vertical bars at 2095 indicate the spread of the updated AR4 IPCC projections for the SRES scenarios (Meehl et al. 2007): the magenta (lighter) bar indicates the range of model projections, mainly accounting for ocean thermal expansion and melting of GIC. The red bar is a potential additional contribution from a dynamic effect of the GIS and AIS. Note that the IPCC AR4 states that "larger values cannot be excluded, but understanding of these effects is too limited to assess their likelihood or provide a best estimate or an upper bound for sea-level rise." Modified from Church, J., et al., 2010: Sea-level rise and variability: synthesis and outlook for the future, in understanding sea-level rise and variability. *Understanding Sea-Level Rise and Variability.* J. Church, P. L. Woodworth, T. Aarup, and S. Wilson, Eds., Wiley-Blackwell, 402–419, ISBN: 978-1-443-3451-7.

occur, for example, from multiple large volcanic eruptions, which could significantly reduce ocean heat content. There is also an inadequate understanding of long-term variations in solar forcing and of low-frequency natural variations in climate system heating and cooling.

The focus on deterministic model predictions, which are the basis of most of the recent climate change assessment and impact studies (even those based on quasi-statistical approaches such as ensemble studies), however, are hampering our ability to assess the true probabilities of climate change (Dessai et al. 2009). As a consequence, the risk associated with future sea-level hazards may be underestimated, eventually misguiding adaptation. As emphasized by McMichael et al. (2006), modeling cannot be an exact science, as the models themselves are hypotheses. As just one incompletely understood issue, there is considerable uncertainty about the future trajectories for greenhouse gas emission, e.g., one of the key human climate forcings, which together with residual uncertainties about the sensitivity of the climate system to these trajectories produces a wide range of plausible trajectories for GT and regional temperatures. As the human climate forcing continues, the probability of exceeding critical thresholds and causing rapid changes in climate and environment should be expected to also increase (Harrison and Stainforth 2009).

If we cannot skillfully predict sea-level changes in the coming decades, what would be a more prudent approach? An assessment of risks from any plausible change in sea-level can provide guidance (Donner 2012). For this approach, considering the statistical characteristics of past behavior of the Earth system is a starting point. Compared to the large fluctuation in GT and GSL over the last million years and more, the Earth system has been in a mediocre state over the last few thousand years with very small changes. In 'Mediocristan,' single extremes do not matter; it is the integral over the gradual changes that count (Taleb 2010). However, human climate forcing and long-term climate variability could push the Earth system into a state where extremes are more common and much larger. In 'Extremistan,' single events are crucial. For example, a rapid melting of a large portion of the GIS or AIS would constitute such an extreme event. Similarly, a significant change of ocean circulation could catapult the Earth system into a different state with severe consequences for ecosystems and humanity.

While we are used to our socio economic system being in Extremistan, with the Great Depression, the First and Second World Wars, and the Internet being examples of extreme events that determined the future, we do not have this view on the development of the Earth system. In our planning, we basically rule out that extreme events can have a determining impact. Climate modeling is based on the assumption that the planet is in Mediocristan. The multi-decadal climate models have demonstrated no skill at predicting extreme events leading to a change in the state of the system. The models are not able to model past extreme events. For a system that has the potential to be in Extremistan, these models are almost useless as a basis to determine the PDFs of hazards. For a system in Extremistan, so-called 'Black Swan' events have a larger impact on the system's future than the gradual changes. Black Swan events are improbable, high-impact events that (1) are outside our experience; (2) have an extreme impact; (3) can be explained after the fact Taleb (2010). Considering the dependence of our civilization on the coastal zone and coastal ecosystems (Edwards 2008) and the fact that we are still migrating into the coastal zone, a sea-level Black Swan, that is a rapid rise exceeding all expectations, would be truly disastrous. Coastal ecosystems have the ability to adapt to slow changes in mean sea-level through migration, but for most systems, there will be a threshold for the speed of changes with the systems not being able to adapt to changes at a pace above the threshold.

There is a chance that the current scientific discussion of GSLR is preparing the ground for a 'Black Swan' event. Recent assessments of GSLR in the twenty-first century have been based on models calibrated to the recent past (**Figure 3**). These models, however, are incapable of predicting the rapid sea-level rise events that have taken place many times over the last one million years, with changes during one century exceeding present-day rates by a factor of 50 and more. The discussion of the upper limit for the twenty-first century is also based on the recent past and assumptions, excluding the rapid rises that are documented in the paleo-records. This bias to low estimates and low upper bounds creates a mindset that is no longer open for the improbable, high-impact event, e.g., the Black Swan. Another reason why the last few thousand years with relatively stable condition may not be a good basis for assessing the future, is the fact that, humanity over the last few hundred years has re-engineered the Earth system, with the most dramatic changes during the last decades, as human population continues to grow and increasingly alters the environment (Syvitski 2012, e.g.,). A more comprehensive look at the statistical properties of the Earth system in terms of century-scale GT, GSL, and LSL changes is needed.

4.14.3.2 Probability Density Function of GSLR

In order to assess the character of the sea-level rise Black Swan, we need to consider the PDFs of century-scale changes in relevant parameters and relate these to plausible changes in these parameters for the twenty-first century. There are many relevant parameters, but we will consider here only two examples, namely century-scale GSLR and Global Temperature Rise (GTR) (denoted here as GSLR_{100} and GTR_{100}, respectively). Considering that over the last 50 years, the world ocean accounts for 90% of the global warming (Levitus et al. 2012), we have to acknowledge that GTR is a poor indicator of GSLR, but many discussions focus on GTR. For example, ocean heating and continental glacier changes cannot be directly related to the GTR. Ocean heating measured in Joules depends on the process in which heat is transferred to the ocean, and only weather patterns (temperature, precipitation, cloud cover) and other environmental changes in the ice-covered region matter in terms of melting and runoff into the sea.

There is very little information available to determine the location-dependent PDF of LSL rise for many locations. For GSL, information on changes over the last 400 000 to 800 000 years is available from studies of several proxies (see, e.g., Hansen et al. 2008; for an overview). In the following, we have used observed Antarctic temperature (Vimeux et al. 2002) as a proxy for GT to determine time series of GTR_{100} (**Figure 6**) for the last 425 000. The comparison of the observed Antarctic

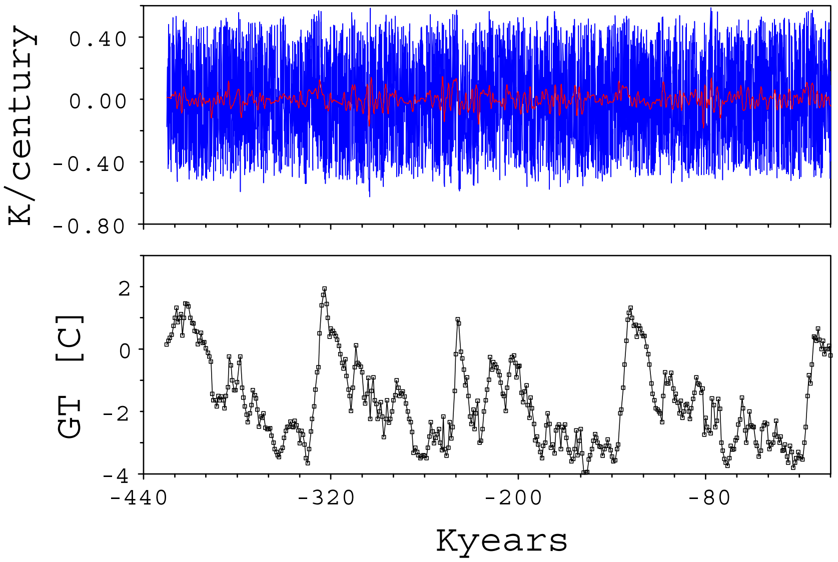

Figure 6 GT and GTR_{100} over the last 425 000 years. Lower diagram: observations of Antarctic temperature changes (Vimeux et al. 2002), which compare well to the GTR modeled by Hansen et al. (2008). Upper diagram: GTR_{100}; the red curve is the GTR_{100} determined from a spline interpolation of the lower curve; the blue line has a random fluctuation of the GTR_{100} around the GTR_{1000} of ±0.4 K/century. See text for details.

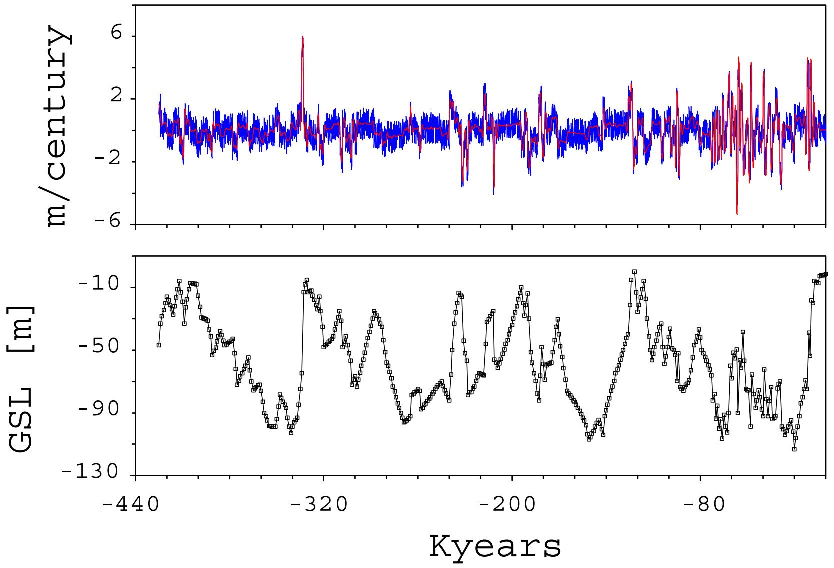

Figure 7 GSL and $GSLR_{100}$ over the last 425 000 years. Lower diagram: GSL determined from Red Sea sediments Siddall et al. (2003). Upper diagram: $GSLR_{100}$; the red curve is the $GSLR_{100}$ determined from a spline interpolation of the GSL curve; the blue line has a random fluctuation of the $GSLR_{100}$ around the $GSLR_{1000}$ of ±1 m/century. See text for details.

temperature to model GT (Hansen et al. 2008) show that the fluctuations of the Antarctic data is larger than the modeled GT, thus leading to a slightly more variable GTR_{100}. For the GSL, we use data provided by Siddall et al. (2003) to determine a time series of $GSLR_{100}$ (Figure 7). We then use these time series of GTR_{100} and $GSLR_{100}$ to determine the PDFs of GTR_{100} and $GSLR_{100}$ (Figure 8).

For most of the period considered, the data available for GT and GSL has a temporal resolution of 1000 years or less. In the first step, we use a spline interpolation of the data to determine the century changes. However, the spline interpolation very likely is too smooth, thus resulting in a PDF far too narrow. Particularly the temperature data lead to a very narrow PDF confined to the interval between ±0.25 K per century. In order to get a better assessment of the century-scale rates, we have to make assumptions with respect to the deviation of these rates from the millennium averages. For GT, we assume that GTR_{100} fluctuates randomly around the millennium average with ±0.4 K. The random fluctuation drastically changes the PDF, and it appears that the assumed amplitude of 0.4 K per century is at the upper limit of what is consistent with the available data.

For sea-level, the values for $GSLR_{100}$ determined from a spline interpolation of millennium rates cover the interval between -5 m per century and $+7$ m per century, with larger positive rates (rise) being more likely than larger negative rates. For GSLR, we also test the effect of adding a random fluctuation of $GSLR_{100}$ around $GSLR_{1000}$ and assume a fluctuation of ± 1 m. For GSL, adding a random fluctuation with this amplitude does not significantly change the PDF.

Comparing the twentieth century change in global temperature of (0.74 ± 0.18) K (Meehl et al. 2007) to the PDF for GTR_{100}, it is clear that this rise falls outside the PDF for the last 425 000 years. More drastically, the IPCC AR4 predictions for several emission scenarios are far outside the range of GTR_{100} documented in the paleo-data. There are two alternative interpretations: (1) the predictions are inaccurate, and by far, overestimate of the GTR_{100} for the twenty-first century possible in the Earth system or (2) the predictions are realistic, in which case the Earth history of the last 450 000 years provides no useful analog for the impact of the predicted GTR_{100} for the twenty-first century. In particular, if alternative (2) were correct, many ecosystems would not be able to cope with the unparalleled speed of GTR_{100}. For coastal ecosystems, any such rapid change would lead to double stress from changes in the region's weather patterns and from rising sea-levels.

Do we have indications which of the two alternatives are more likely? The fact that many of the characteristic parameters of the Earth system (including atmospheric constituents such as CO_2N_2O, and CH_4, damming of rivers, water use, nitrogen deposition, ozone deletion, urban population, ocean ecosystems, coastal zone structures, ocean zone biogeochemistry, loss of tropical rain forests and woodlands, and global diversity; see e.g., Steffen et al. (2004) and **Figure 1** in Syvitski (2012)) have already attained values outside their range of variability during the last one million years or more seems to support alternative 2. It is interesting to note that, for example, the CO_2 concentration of 385 ppm observed in 2008 exceeds the previously occurring maximum of 300 ppm observed during the last 800 000 years by 65% of the total Glacial-Interglacial Range (GIR) of 130 ppm during this time (Karl et al. 2009). The speed of change in many Earth system parameters is also unparalleled. For example, while during the last million years, maximum changes in CO_2 on the order of 100 ppm took place over thousands of years, humanity accomplished this in less than three centuries. Under these unparalleled conditions, the response of the climate system to the combined changes in the Earth system may also exceed all rapid responses documented in the paleo-records. However, this does not exclude alternative 1.

The twentieth century $GSLR_{100}$ of (0.2 ± 0.1) m per century falls well into the PDF for $GSLR_{100}$ (**Figure 8**). Similarly, the IPCC AR4 prediction for twenty-first century thermal expansion and for combined GSLR due to thermal expansion, ice sheet, glaciers, and land water storage contributions are within the more or less central domain of the PDF. However, considering that the predicted GTR_{100} is far outside any past experience, there are unresolved questions as to their value to assess the risks associated with GSLR and LSLR in the coming decades.

Is there a relation between GTR_{100} and $GSLR_{100}$? Using the data determined from the spline-interpolated curves, we find no correlation between GTR_{100} and $GSLR_{100}$. One reason for this lack of correlation could be large errors in the timing of the rapid changes in GT and GSL. The proxies used to determine these curves have significant uncertainties in time. Another reason could be the complex nature of the Earth climate systems, where GSL changes do not lead to correlated GSL changes. If, for example, an increase in GSL leads to changes in ocean circulation with impacts on the latitudinal temperature and precipitation distribution, then an increase in GT could lead to increasing ice sheets and a fall in GSL. The high correlation between IPCC AR4 predicted 21st GTR and GSLR is an indication of the models not reflecting the complexity of the climate system.

How much does the location-dependent $LSLR_{100}$ deviate from $GSLR_{100}$? The answer to this question helps to assess the probability of large rises along parts of the coasts. In the following, we will first review the science basics of LSL changes and analyze the relevant processes. This will provide the basis to assess both the range of plausible changes and the spatial variability.

4.14.3.3 The Cumulative LSL Equation

As mentioned above, Earth system models available today are not capable of modeling all LSL forcing processes and predicting LSL changes. However, the scientific understanding of the link between individual global, regional, and local processes and LSL changes is well developed. Therefore, a local approach can be used to describe the relation between forcing processes and LSL. For our purpose, it is helpful to separate the equation describing LSL as a function of the various forcing processes into a high-frequency and a low-frequency part (Plag 2006a). For the assessment of impacts, the combined effects of the high-frequency and low-frequency part of the LSL equation are important.

LSL variations ξ can be written as:

$$\begin{aligned}\xi(\vec{x},t) &= W(\vec{x},t) + T(\vec{x},t) + A(\vec{x},t) + S(\vec{x},t)\\ &\quad + C(\vec{x},t) + F(\vec{x},t) + I(\vec{x},t) + G(\vec{x},t)\\ &\quad + L(\vec{x},t) + P(\vec{x})(t) + V(\vec{x},t),\end{aligned} \qquad [5]$$

where t is time, t_0 an arbitrary time origin, and ξ is given relative to an arbitrary zero level (modified from Plag (2006a)). Here we include the processes W: waves, T: tides, A: LSL changes caused by atmospheric forcing, S: steric changes, C: ocean circulation, F: freshening due to melting of sea and land ice, I: mass changes in the large ice sheets, G: mass changes in the continental glaciers and ice caps, L: land water storage changes, P: postglacial rebound, V: vertical land motion other than postglacial rebound or land motion caused by other surface loading. Some of these processes lead to predominately short-period variations (e.g., waves), while others are pre-dominantly long-period to secular in nature (e.g., postglacial rebound caused by the melting of the ice sheets of the last ice ages). Most terms have both short and long-period variations, although with different significance (**Table 1**).

Equation [5] illustrates the complex nature of LSL variations as the result of processes in the global water and energy cycles merged with geodynamic processes and, recently, anthropogenic activities. The processes separate into two large groups, namely those that are mainly volume changes of the ocean

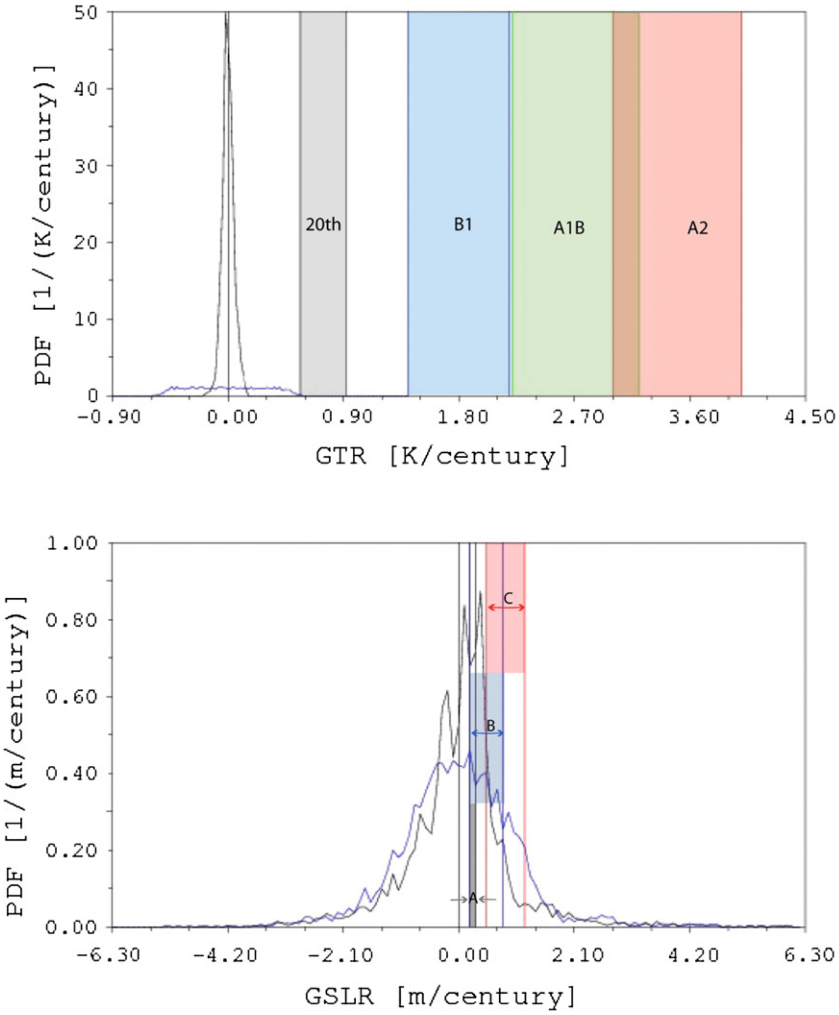

Figure 8 Probability density function of $GSLR_{100}$ and GTR_{100}. In each diagram, the black curve is the PDF based on the spline-interpolated millennium averages; and the blue curve the PDF determined from the rates including the random variation of the century rates around the millennium averages. The vertical lines indicate current rates and twenty-first century predictions. Left: PDF for GTR_{100}; A2, A1B, and B1 are the SRES emission scenarios used in IPCC AR4 (Meehl et al. 2007). Right: PDF for $GSLR_{100}$. A: twentieth century observed GSLR (Bindoff et al. 2007); B: predicted twenty-first century GSLR due to thermal expansion (Meehl et al. 2007); C: plausible twenty-first century GSLR including contributions from ice sheets, glaciers, and land water storage.

water (and thus affect GOV, but not GOM) and those that are associated with significant mass redistribution in the global water cycle (and thus may also affect). Before we address our ability to predict LSL variations on century time scales, we first provide the theoretical background for LSL changes caused by mass redistribution and describe the current knowledge in terms of current contributions and predictions for each of the processes included in eqn [5].

4.14.3.4 Mass-Induced LSL Variations

Processes involving redistribution of mass in the water cycle are all associated with viscoelastic–gravitational effects on LSL, leading to very distinct spatial and temporal patterns of LSL variations caused by these processes. In order to emphasize the importance of the fundamental relationship between any mass transport in the global water cycle and the LSL, we consider the case where the GIS mass increases and the AIS melts with the two changes being exactly in balance. This mass movement will not change the GOM or induce any GSL change, but LSL will fall significantly over large regions of the southern oceans and increase over large parts of the northern hemisphere. Thus, LSL changes caused by mass redistribution in the global water cycle depend crucially on where the mass redistribution takes place (as reconfirmed by Mitrovica et al. 2009).

The governing equation that links mass redistribution to LSL variations ξ (first introduced by Farrell and Clark 1976) can be written as:

$$\xi(\vartheta,\lambda,t) = c(t) + \int_{-\infty}^{t}\int_{0}^{\pi}\int_{0}^{2\pi} G(\vartheta,\lambda,\vartheta',\lambda',t-t') \qquad [6]$$

$$\frac{\mathrm{d}}{\mathrm{d}t'}\{O(\vartheta',\lambda',t')\rho_{\mathrm{W}}\xi(\vartheta',\lambda,t') + [1-O(\vartheta',\lambda',t')]\rho_{\mathrm{L}}\eta(\vartheta',\lambda,t')\}\sin\vartheta'\,\mathrm{d}\lambda'\,\mathrm{d}\vartheta'\,\mathrm{d}t',$$

Table 1 Processes contributing to LSL variations. Upper part: processes with significant short-period variations. Lower part: processes with negligible short-period variations

S.	*Process*	*Short-term*	*Long-term*	*Comment*
W	Waves	From seconds to more than 30 min (tsunamis)	Changes in wave energy due to climate	Relevant for coastal erosion
T	Tides	Monthly, fortnightly, diurnal, semi-diurnal, and shorter periods	Semi-annual, annual, and nodal tides	Changes due to climate are very small
A	Atmosphere	From seconds to months	Intraseasonal to secular; with multi-decadal variation in mean air pressure distribution and wind field changes impacting sea level	Can create multi-decadal trends on the order of several millimeters per year

S.	*Process*	*Long-term*	*Comment*
S	Steric	Most changes are on seasonal time scales, with multi-decadal to secular trends	Can contribute on the order of 50 cm per century
C	Circulation	Some interannual to multi-decadal variations; long-term changes in ocean circulation, including a significant slowing or an interruption of the thermohaline circulation	Long-term changes could have significant impacts on the DST and a feedback on regional climate
F	Freshening	Contributes to the seasonal cycle in sea level	A significant long-term reduction of sea ice would impact ocean salinity and GOV
I	Ice sheets	Contribute to the seasonal changes in Global Ocean Mass (GOM) as well as interannual to multi-decadal variations	The ice sheets are the main source for potentially large and rapid GSLR, with large spatial variations in LSLR (fall in the near-field and rise in the far-field).
G	Glaciers/ice caps	Contribute to seasonal changes in GOM; are a main contribution to present-day GSLR	Could contribute to increased GSLR; the spatial pattern in LSLR is complex due to the spatial distribution
L	Land water storage	Contributes to seasonal, interannual, and multi-decadal changes in GOM	Land use changes such as deforestation, irrigation, water reservoirs contribute to long-term changes in GOM; permafrost melting also may have an effect
P	Postglacial rebound	Produces significant secular land uplift in and around formerly glaciated areas and small subsidence in some far-field regions	
V	Vertical land motion	Earthquakes can lead to significant (order 1 m or more) sudden vertical displacement; tectonic processes and natural and anthropogenic subsidence can cause transient and secular vertical displacements of 250 mm year^{-1} and more	

Table 2 Regimes of the coastal zone

Regime	*Description*
Dry land	Land above the high water mark, which is rarely inundated by storm surges.
Littoral zone	The littoral zone extends from the high water mark to shoreline areas that are permanently submerged.
Estuarine	Estuarine regimes are enclosed or semi-enclosed coastal water bodies that are influenced by freshwater input that reduces salinity to below 3.0% during at least two months of the year. These waters are intimately linked with their watersheds, receiving nutrients, materials, and freshwater during a significant part of the year.
Freshwater influenced	Freshwater-influenced regimes are coastal waters that have no distinctly enclosing morphology, yet receive a significant amount of freshwater input from land during at least parts of the year. In such cases, an unenclosed marine water column may be influenced by freshwater in the form of an active river plume, an overlying freshwater lens or a groundwater seep discharge. They often may have surface characteristics of estuaries, but deeper waters may be completely marine.
Nearshore marine	Nearshore marine regimes are those coastal waters that are truly marine in character ($>$3.0% throughout the year) and not influenced by significant freshwater. The nearshore marine regime extends from the land margin to the 30 m depth contour.
Neritic	The neritic regime is the region of marine waters ($>$3.0% throughout the year) between the 30 m depth contour and the continental shelf break, which occurs at approximately at 200 m water depth.
Oceanic	The oceanic regime represents the marine realm beyond the continental shelf break, generally occurring at 150–300 m of water depth at the seaward edge of the continental shelf. These waters can range to several thousands of meters depth. The marine waters of the oceanic regime are sufficiently distant from land that they receive little or no influence of freshwater, nutrient and sediment inputs, except around large islands.

Modified from Madden, C. J., and K. L. Goodin, 2007: *Ecological Classification of Florida Bay Using the Coastal Marine Ecological Classification Standard (CMECS)*, Tech. Rep., NatureServe, Arlington, Virginia, to suit the purpose of the LSLR discussion.

where ϑ, λ, and t are co-latitude, longitude, and time, respectively, ρ_W and ρ_L are the densities of the ocean water and the load on land (water or ice), respectively, G is the Green's function for LSL defined below, O the ocean function, defined to be one over ocean and zero over land, and η the accumulated ice load change due to mass added or removed from land. $c(t)$ is determined such that mass is conserved. ξ as defined by eqn [6] is a continuation of LSL onto the continents, and the true LSL has to be defined as $\hat{\xi} := O\xi$. The function ξ has the important advantage over $\hat{\xi}$ of being continuous at the coastlines. The mass-LSL eqn [6] assumes instantaneous distribution of the water in the global ocean and thus is only valid for sufficiently long time scales. Hydrodynamic studies showed that the equation is appropriate at annual to longer time scales (see Plag 2006b; and the reference therein). Over the last two decades, eqn [6] has been augmented by several groups (e.g., Milne et al. 1999), with the most comprehensive version (Mitrovica and Milne 2003; Kendall et al. 2005) accounting for melt-water inundation of deglaciated areas and rotational effects of LSL changes (pole tide) in a self-consistent manner. There are many technical details related to the use of eqn [6], including the Earth model, the ice history, and numerical procedures which are discussed e.g., in Plag et al. (1998); Mitrovica et al. (2010).

The mass-LSL eqn [6] has been applied extensively to studies of LSL changes caused by the ice ages and the subsequent Postglacial Rebound (PGR) (see Mitrovica et al. 2006; and the references therein). In the PGR studies, main focus has been on the viscous part and the determination of the radial viscosity profile of the Earth mantle (e.g., Peltier 1974; Farrell and Clark 1976; Nakada and Lambeck 1987; Mitrovica et al. 1994a,b; Vermeersen et al. 1996). There are still considerable inter-model differences in predictions of present-day PGR signals in LSL, surface displacements, geoid, and rotation (e.g., Chambers et al. 2009), which originate mainly in differences in ice history and the treatment of rotational effects. Using eqn [6] to describe the relation between present-day mass changes and LSL so far has been restricted to a few examples (e.g., Plag and Jüttner 2001; Mitrovica et al. 2001; Plag 2006a; Mitrovica et al. 2009; Bamber et al. 2009). It has to be noted that in many scientific communities outside the solid Earth sciences, the very large spatial variations of LSL compared to the global average are not well known and often ignored in GSLR impact studies.

Major mass redistribution in the global water cycle can result from significant mass loss from ice sheets, ice caps, and glaciers. Net ice-mass depletion of land-based ice will add to the net water mass in the ocean, unless it is intercepted by surface water or terrestrial storage reservoirs. The mass loss is accomplished by direct climate forcing (through changes in precipitation, melt rate, etc) and by dynamic changes (e.g., subglacial sliding, iceberg calving) that can be indirectly and non-linearly influenced by climate. Dynamic changes can act to accelerate mass loss from glaciers and ice sheets, but generally not to retard it. If these mass changes are known sufficiently, for example, from model predictions, then the resulting LSL variations can be calculated using eqn [6]. However, there are differences in the LSL admittance functions (e.g., the global pattern of LSL change caused by a 1 m unit ice change over an ice sheet or glacier normalized by the globally averaged LSL change) computed by different groups for the GIS and AIS. For example, the global admittance functions for the AIS and GIS computed by Plag and Jüttner (2001) exhibit larger spatial variability than those computed by Mitrovica et al. (2001, 2009) and Vermeersen et al. (2008, personnel communication). Due to a lack of abundant modern observations close to sufficiently large and rapidly changing ice masses, a comparison of near-field concurrent LSL changes to predictions has not been possible so far. Thus, the solutions of the elastic part of eqn [6] have not been validated against observations. Results of a recent study of near-field vertical uplift induced by present-day ice load changes in Svalbard (Kierulf et al. 2009) indicate near-field values for the LSL admittance function in the range of −50 to −70, which would require a much larger spatial variability of the LSL admittance function than predicted by Mitrovica et al. (2001, 2009), but somewhat smaller than what Plag and Jüttner (2001) predict. The origin of the inter-model discrepancies can be in the Earth model itself; the computation of the Load Love Numbers (LLNs) and the parameterization of the Earth model for this computation; the convolution of the Green's function with the load anomalies; and the solution of the mass-LSL equation. The availability of increasingly dense GPS networks in the vicinity of rapidly changing ice loads provides a unique opportunity to identify the origin of the inter-model differences and to resolve them.

Best estimates for the total present-day volume of land-based ice are: for the East Antarctic Ice Sheet (EAIS), ca. 70 m Sea-Level Equivalent (SLE); for the West Antarctic Ice Sheet (WAIS), ca. 3.3 m SLE (Bamber et al. 2009); for the GIS, ca. 7.2 m SLE (Bamber et al. 2001); and for the aggregate of all other glaciers and ice caps world-wide, ca. 0.6 m SLE (Radic and Hock 2010). Current and next-century contributions from the EAIS are believed to be comparatively small, while the WAIS and GIS are large present-day sea-level contributors, at ca. 0.5 and 0.74 mm year^{-1} SLE, respectively (Rignot et al. 2008a,b); The total aggregated contribution of GIC to SLE volume is small, but the GIC are presently a very large source of sea-level rise, at ca. 1.1 mm year^{-1} (Meier et al. 2007), although Jacob et al. (2012) reach a much reduced estimate of 0.41 ± 0.08 mm year^{-1}. The large loss rate from GIC is diminishing the source volume at a rate of close to 0.2%, so reservoir depletion will eventually reduce the GIC flux, but not significantly in the near term (next century). Jacob et al. (2012) estimate the current total contribution of GIC and the two large ice sheets to be 1.48 ± 0.26 mm year^{-1}.

Prediction of GSL from land-ice sources depends critically upon numerical simulations and requires knowledge of atmospheric and oceanic forcing, as well as, geometric landscape boundary conditions. While significant progress has been made in ice sheet numerical modeling capacity, robust operational models do not yet exist for prediction. Chief among obstacles to be overcome are a lack of knowledge of the processes of subglacial sliding (boundary slip) and iceberg calving. Comprehensive global predictive modeling is also hindered by a lack of basic information for ca. 40% of the GIC area, including glacier and ice cap volume, basal topography, and location of marine-based outlets (Pfeffer et al. 2008).

4.14.3.5 Impacts of Sea-Level Rise

Coastal zones are complex and dynamic environments with many interactions between physical processes, such as waves and tidal currents, imposed on underlying geology, the availability of sediments, and changes in sea-level. The spatial variations in these factors lead to a wide variety in the characteristic coastal landforms, including beaches, cliffs, and barrier islands. The general response of coastal landforms that can occur in response to LSLR are widely understood (e.g., FitzGerald et al. 2008), but determining precisely how and what changes occur in response to a specific rise in sea-level has been difficult, due to the wide range of spatial and temporal scales involved in the processes that cause the LSLR and interact at a given coastal location. Consequently, it has been difficult to determine a quantitative relationship between LSLR and shoreline change. No scientific consensus has been reached as to whether or not observed shoreline changes can be quantitatively related to LSLR (Gutierrez et al. 2009; and the references therein).

Focusing on coastal ecosystems, the impacts of LSLR (in combination with other sea-level hazards) can be broadly classified into effects of (1) wetland loss, (2) salinity increases, and (3) beach erosion (Titus 1988). LSLR is a coastal hazard with the potential to amplify the impacts of waves, storm surges, shoreline erosion, wetland loss, and saltwater intrusions. Even a small increase in LSL can change the statistics of extreme sea-level events significantly. Depending on the coastal topography, what today is a 100-year flood could easily become a 10-year flood or an even more frequent flood.

Many recent assessments of the coastal impacts of LSLR have focused on identifying land located at elevations below plausible LSL trajectories (e.g., Anthoff et al. 2006; Rowley et al. 2007; CCSP 2008). While these elevation-based analyses are an important first step in the understanding of the potential impacts of LSLR, this approach only reveals a part of the potential consequences for the coastal zone. Changes in the coastal zone are driven by interrelated, complex processes including waves, tsunamis, storms, LSLR, sediment transport, and biological processes acting on a wide range to temporal scales. As a result, the response of a coastal region to LSLR results from a combination of one or more of the processes in the following broad categories (e.g., FitzGerald et al. 2008): increased frequency of storm flooding; land loss due to permanent inundation of low-lying lands; land loss due to erosion of beaches, dunes, and cliffs; barrier island breaching, segmentation, and migration; wetland conversion to open water, migration inland, and accretion through increased flooding; expansion of estuaries; saltwater intrusion into freshwater aquifers and surface waters.

Even the lowest GSLR scenarios considered in the IPCC AR4 would have a wide range of impacts on many coastal environments and infrastructure. Effects are likely to include coastal erosion, wetland and coastal plain flooding, salinization of aquifers and soils, and a loss of habitats for fish, birds, and other wildlife and plants (Meehl et al. 2007). IPCC estimates that a continuation of the current GSLR likely would lead to a loss of as much as 33% of coastal land and wetland habitats in the next hundred years. Considering that the impacts in most areas do not scale linearly with the sea-level rise (Craft et al. 2009), any increase in the rate of GSLR could increase land and habitat losses dramatically, putting a very large number of wetland and swamp species at serious risk. In the polar regions, the retreat of coastal sea ice is already threatening species that depend on the existence of sea ice with extinction (Arctic Climate Impact Assessment (ACIA) 2004).

4.14.3.6 Coastal Protection

If coasts come under increasing threats from inundation, flooding, and increased erosion, mitigation of LSLR impacts and adaptation strategies are needed. Coastal protections, such as sea walls and dikes, have been constructed since Roman times to protect human settlements from the sea. In the twentieth century, large parts of the low-lying coasts have been protected with massive so-called 'hard' engineered defenses, particularly in Europe and North America. Disasters caused by storm surges such as the 31 January 1953 event in The Netherlands, Belgium, and the United Kingdom triggered many national programs to strengthen coastal protection. This 'hold-the-line' approach and the security provided by these protections has enabled and encouraged development of coastal regions otherwise at risk of flooding (**Figure 9**). Following this line, many economic assessments conclude that the only viable strategy is to improve coastal protection by improving the engineered defenses (e.g., Schwerzmann and Mehlorn 2009).

It is, however, now increasingly recognized that these hard defenses are unsustainable for several reasons (Turner et al. 2007). In the case of failure, the ensuing disaster is severe, as was illustrated by the impact of Hurricane Katrina in New Orleans. In many cases, the protections themselves have led to a reduction or loss of intertidal habitat, reducing also the natural protection these compartments often provide. Coastal habitat migration, loss and gain in response to sea-level changes have occurred throughout geological times. However, the perspective for the twenty-first century is different due to the presence of developed shorelines, which introduces a new barrier for habitat migration. Moreover, the rate of LSLR could be at the upper end of the spectrum (see Section 4.14.3.2).

We can distinguish between five generic strategies for dealing with coastal defense in areas with rising sea-level, with different impacts on ecosystems, society, and economy (**Figure 10**). (S1) Do nothing: inaction eventually will lead to abandonment and destruction of infrastructure built within the zone inundated by the rising sea. This will leave room for the tidal zone to migrate inland. (S2) Managed realignment: plan infrastructure in the potentially inundated areas such that it can be realigned if sea-level rise and shoreline transgression requires this. This also leaves room for the tidal zone to migrate inland. (S3) Hold-the-line: hard engineered protections (seawalls, dikes, barriers) are constructed to prevent transgression of the shoreline. Over time, this eliminates the tidal zone completely. (S4) Progression: new defenses are constructed seaward of the original shoreline, thus creating new land and protecting existing infrastructure. This approach generally leads to reorganization of ecosystems. (S5) Soft intervention: the ability of ecosystems to migrate vertically is utilized to raise parts of the tidal zone and the adjacent land vertically. Not all of these strategies are applicable to all sites.

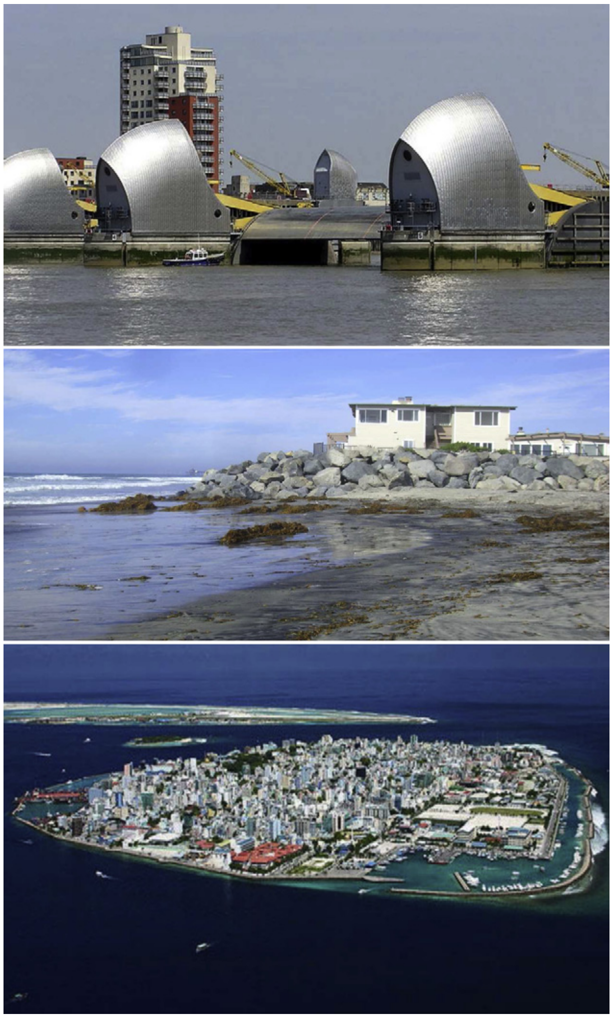

Figure 9 Examples of coastal protection and developments. Upper picture: the Thames Barrier, London, U.K., which is protecting more than 800 000 houses in the flood plane, including crucial infrastructure such as about 50 hospitals; Middle: Imperial Beach, California, where houses at a transgressive beach in a tsunami-prone area are protected with boulders, while the beach is transgressing past the developed coastline. Bottom: The island of Malé, capital of the Maldives Islands in the Indian Ocean. The maximum elevation is 2.4 m, and population is around 100 000. This extreme example of the hold-the-line (or even progression) strategy (**Figure 10**) required a seawall around the entire island.

For example, in urban coastal areas such as London, New York City, Jakarta, Shanghai, and Malé, Maldives (Figure 9), the strategies (S1) and (S2) may not be viable alternatives for economic and social reasons. For urban areas in deltas, storm surge barriers (S3) are an option to handle extreme events. The protection of world heritages (such as the city of Venice) may also require floodgates with potentially significant impacts on the marine ecosystems. The applicability of the strategies also depends on the rate and amount of LSLR. The very rapid subsidence in parts of Jakarta eventually may only leave (S2) as an option, while a significant LSLR only will leave (S1) for the Maldives. In rural coastal areas, the negative ecological impact of (S3) or (S4) may exceed the social and economic impact of living within the future flood plain resulting from a projected LSLR. Economic and social conditions impact the choice, too. In many developing countries, (S1) and partly (S2) are the only viable options.

Considering the impact on ecosystems, strategies (S1), (S2), and (S5) are the least impacting. In general terms, the potential ecological effects of strategies (S3) and (S4) involving hard coastal protections are understood (e.g., Seitz et al. 2006). Likewise, the impact of an LSLR on ecosystems has been studied abundantly. However, few studies on the combined effect of LSLR and coastal protections have been published (Shellenbarger Jones et al. 2009). Nevertheless, it can be stated that hard engineered protection combined with sea-level rise would narrow down or eliminate most of the tidal zone and the adjacent wetlands. Similar to developed coastlines, these protections would prohibit inland migration of the sea-side coastal zone compartments in response to LSLR.

Turner et al. (2007) considered managed realignment as an alternative to maintaining 'hard' defenses for the protection of land from LSLR. In this approach, the engineered defenses are deliberately breached, thus allowing the coastline to recede to a new shoreline further inland, where a new intertidal habitat is created providing natural protection from flooding and erosion. Their cost–benefit analysis shows that managed realignment can be economically more efficient than holding-the-line, if the time period considered is sufficiently long (generally greater than 25 years). Particularly for rapid rates of LSLR, managed alignment may be the only viable options both for ecosystems and for human population.

4.14.4 The Assets: Coastal Ecosystems and Their Services

The assets of the coastal zone include geomorphological features, as well as, coastal ecosystems. Depending on the geological and environmental settings, coastal ecosystems include tidal marshes, tidal forests, aquatic vegetation beds, tidal flats, beaches, cliffs, and estuaries (Shellenbarger Jones et al. 2009). Providing habitat for many species (including many endangered and threatened species), the coastal ecosystems are among the most productive ones and they provide essential ecosystem services that no other ecosystem can provide (Daily et al. 1997; de Groot et al. 2002). These services include not only those processes supporting the ecosystem itself but also many human benefits derived from those processes. The wide range of services include nutrient cycling and uptake, natural water quality improvement, water storage and delivery, flood protection, shoreline erosion control, fish production, and the provision of recreational opportunities helping to promote human well-being.

Wetland plants hold the soil in place with their roots, absorb the energy of waves, and reduce the impact of tidal streams. They provide a buffer to major storm impacts, particularly to damaging storm surges, and thus reduce coastal erosion.

Tidal marshes and mangroves can store flood waters that runoff from upland. By retaining excess nutrients and some pollutants in surface-water runoff from higher dry land before the runoff reaches open water, they provide an important filter service, and reduce sediment that otherwise would degrade

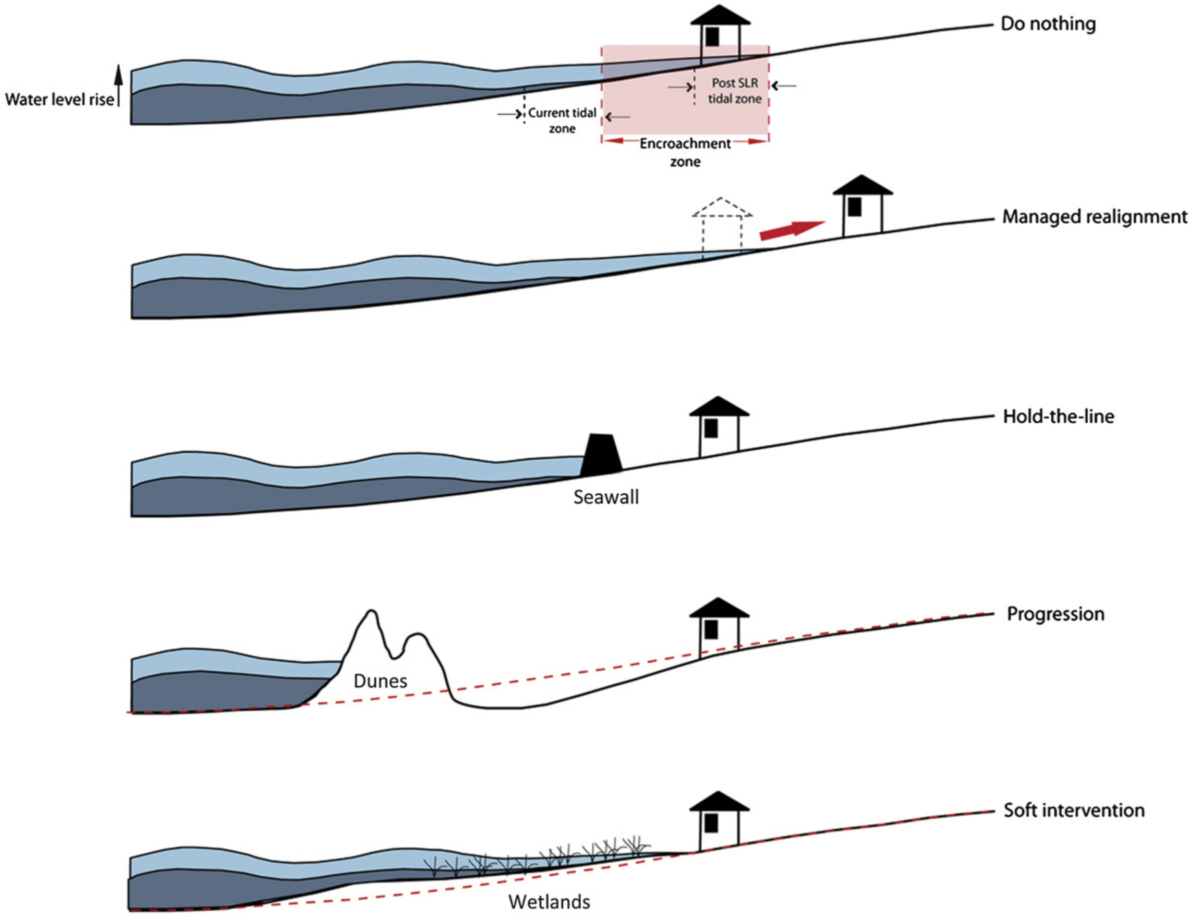

Figure 10 Five generic strategies for coastal management in areas with potentially rising sea levels.

estuarine and adjacent marine compartments and impact fish and amphibian egg development.

Estuarine, marine fish, and shellfish depend on coastal wetlands to survival. The wetlands are critical for juvenile and adult stages of many economically important marine fish and shellfish species. In fact, most commercial and game fish breed in coastal marshes and estuaries. Various birds and certain mammals, many of them with economic value, also depend crucially on coastal wetlands.

For many coastal communities, wetlands, estuaries, and the adjacent marine zone contribute to the economic livelihoods. Coastal wetlands have recreational, historical, scientific, and cultural values, and they offer significant esthetic value to humans. Estimates of the global economic value of all the services coastal wetlands provide are in excess of $1.6 Trillion per year (Costanza et al. 1997). Particularly, the recreational opportunities are economically important. There is an estimated half of international tourists travel to wetlands of all types, particularly those in the coastal zone.

The marine and coastal zone wetlands can be separated into the following:

1. Marine waters: permanent shallow waters less than 6 m deep at low tide; includes sea bays, straits;
2. Subtidal aquatic beds: sea grasses, tropical marine meadows;
3. Coral reefs;
4. Rocky marine shores: rocky offshore islands, sea cliffs;
5. Sand, shingle, or pebble beaches: sand bars, spits, sandy islets;
6. Intertidal mud, sand, or salt flats;
7. Intertidal marshes: salt marshes, salt meadows, raised salt marshes, tidal brackish, and freshwater marshes;
8. Intertidal forested wetlands: mangrove swamps, swamps, tidal freshwater swamp forests;
9. Brackish to saline lagoons and marshes with one or more relatively narrow connections with the sea;
10. Freshwater lagoons and marshes in the coastal zone;
11. Non-tidal freshwater forested wetlands.

Mangroves are an important component of the coastal wetlands. Mangrove distribution in latitude is controlled by temperature. Perennial mangroves generally cannot survive temperatures below freezing, constraining their occurrence to the tropics and subtropics with maximum development between 25 °N and 25 °S. The richest mangrove communities occur in areas where maximum water temperatures exceed 24 °C. The most recent estimates suggest that mangroves presently occupy about 146 530 km^2 of tropical and subtropical coastline (McLeod and Salm 2006). Mangroves provide the entire ecosystem services mentioned above, and they provide income from the collection of mollusks, crustaceans, and fish, and the harvest of firewood, timber, and wood chips.

Despite the recognized value of coastal ecosystems, the loss of coastal wetlands over the last few decades has been severe. The cumulative effects of natural and anthropogenic pressures have turned mangrove wetlands into one of the most threatened ecosystems worldwide. About 50% of the global area has been lost since 1900 and 35% in the past two decades, primarily due to human activities, such as conversion for aquaculture. The global average annual rate of mangrove loss is about 2.1% (Gilman et al. 2006a). Over the last few decades, coastal wetlands were reduced globally by 30%. Protecting wetlands is important for humanities safety and welfare. This was recognized in the last century, and in 1971 the Convention on Wetlands of International Importance, called the Ramsar Convention, was adopted in the Iranian city of Ramsar. The Ramsar Convention's mission is "the conservation and wise use of all wetlands through local and national actions and international cooperation, as a contribution toward achieving sustainable development throughout the world." The definition of wetlands in the Convention is broad, including lakes and rivers, swamps and marshes, wet grasslands and peatlands, oases, estuaries, deltas and tidal flats, near-shore marine areas, mangroves and coral reefs, and human-made sites such as fish ponds, rice paddies, reservoirs, and salt pans. The wise use of wetlands, defined as "the maintenance of their ecological character, achieved through the implementation of ecosystem approaches, within the context of sustainable development," aims at the conservation and sustainable use of wetlands and their resources, for the benefit of humankind.

Coral reefs are very valuable and diverse ecosystems providing food and habitat for many other species. In addition to their ecological services, these systems provide billions of dollars in services including tourism, fish breeding habitat, and protection of coastlines. The coral reefs face many challenges arising from anthropogenic activities such as pollution, destructive fishing, poorly regulated tourism, and ocean acidification, as well as, from changes in local and regional weather, which over the last 30 years have led to the death or severe damage of about one-third of the world's corals (Janetos et al. 2008).

The quest to understanding how shorelines form and how human activities affect these processes has led to the creation of a number of classification schemes (e.g., Anderson et al. 1976; Cowardin et al. 1979; Cowardin and Golet 1995; Kutcher et al. 2005; Madden and Goodin 2007; Lund and Wilbur 2007). Most of the authors group coastal areas into classes that have similar features, as a result of having developed in similar geological and environmental settings. Detailed inventories available for certain regions may characterize the shore zone using shoreline morphology, substrate, wave exposure, and biota and subdivide the coast into more or less homogeneous units (e.g., Berry et al. 2001), while others use less granular and more descriptive approaches (e.g., ACCC 2006).

A separation in the main regimes based on the Coastal Marine Ecological Classification Standard (CMECS) as used in Madden and Goodin (2007) is provided in Table 2. The boundaries of CMECS are explicitly defined from the supratidal zone to the central oceans. For the discussion of LSLR impacts, we also have to include the dry land above the high water mark, to which the supratidal zone and, potentially, other zones relocate in case of the rising sea-level. The CMECS considers the following six levels:

- Level 1: Regime: differentiated by a combination of salinity, geomorphology, and depth;
- Level 2: Formation: large physical structures formed by either water or solid substrate within systems; including geoforms and hydroforms such as lagoons, embayments, deltas, reefs, seamounts, islands, ocean gyres, upwellings, etc.;
- Level 3: Zone: the water column, littoral or bottom; position with reference to the water: whether it is a continuously submerged bottom or at the waterline (littoral), or entirely within the water column (pelagic);
- Level 4: Macrohabitat: mesoscale physical structures that contain multiple habitats;
- Level 5: Habitat: a specific, repeatable combination of physical and other environmental characteristics that tend to co-occur;
- Level 6: Biotope: the characteristic dominant association of attached, sessile, or sedentary biota; the smallest quantum unit of the habitat in CMECS.

4.14.5 Vulnerabilities: Impact of Sea-Level Change and Coastal Protection on Coastal Ecosystems

As mentioned in the introduction, the concept of vulnerability differs between scientific disciplines (Brooks 2003). While we use here the concept mostly applied to natural hazards and their impact on the built environment and the population in this environment, we acknowledge that the vulnerability of ecosystems is comparable to that of social system. For these systems, the concept of a threshold is important, that is, the possibility that the system collapses if a certain stress level is exceeded.

While we can provide a concise typology of the physically defined sea-level hazards (see Section 4.14.3), it is more difficult to define the relationship between a given hazard and the vulnerability and adaptive capacity of a human system or ecosystem, as these depend critically on the nature of the hazard faced. As expressed in Section 4.14.2, vulnerability of a system (human or ecosystem) is time variable and depends on the capability of the system to adapt in a timely manner to changing hazards. It also depends on the level of stress the system is already exposed to.

Most of the coastal ecosystems discussed in the previous section, such as sea grass meadows, coral reefs, rocky intertidal zones, mangroves and other wetlands, and estuarine communities, are structured around sea-level. Many of these ecosystems are already stressed by coastal development, eutrophication, and industrial pollution. These impacts reduce the resilience of the ecosystems to recover from disturbances. A rapid LSLR is a disturbance that many coastal ecosystems might face in the coming decades. There are many unanswered questions regarding the resilience of coastal ecosystems with respect to rapid LSLR.

Human activity has been the major threat to wetlands. This is also true for coastal wetlands. Conversion for aquaculture, pollution through agriculture, industrial development, and urban and suburban sprawl in the coastal zone has caused the greatest losses of coastal wetlands. In many areas, the biggest source of loss for freshwater coastal wetlands is from urban sprawl. In some areas, the primary source of saltwater wetland loss is a rise in LSL caused by land subsidence associated with mining of oil, gas, and groundwater. Coastal protection and urban development often narrow down the area in which wetlands can exist or migrate into, if changes in the shoreline due to erosion or LSLR require this.

Estuarine wetlands are dependent upon freshwater inflow from rivers. In some estuaries, freshwater inflow has been reduced through river regulations and rerouting. In many deltas, sediment influx is needed to compensate for subsidence of the delta, and river regulations often reduce the influx, leading to subsidence and the permanent drowning of wetlands. An example are the Everglades in Florida, where human interventions changed the freshwater influx (Walker and Salt 2006), and LSLR increases the salt content of existing bodies of freshwater. Local rainfall also has been reduced in this region, at least in part due to land use change in the Everglades area (Marshall et al. 2004), with a resultant reduced flux of freshwater into the coastal waters.

LSLR would add stress to the already stressed coastal wetlands. The main vulnerability of coastal ecosystems to LSLR result from changes in the physical and dynamical environment, leading to increased coastal erosion, more extensive coastal inundation, and higher storm-surge flooding; changes in the location of the different regimes through landward intrusion of sea water in estuaries and aquifers; inhibition of primary production processes through elimination of crucial ecosystems. It is important to note that most of these impacts do not scale linearly with LSLR (Craft et al. 2009).

Other climate-change related processes can increase the stress, e.g., through changes in surface-water quality and groundwater characteristics, changes in the distribution of pathogenic microorganisms, also in combination with higher sea surface and sea water temperatures, and, for the polar regions, reduction of sea-ice cover.

Coastal wetlands have two main adaptation strategies: vertical migration and horizontal migration. Vertical migration requires sufficient influx of sediments that can be captured within the ecosystem and helps to raise the base to compensate for an LSLR. Migratory organisms will most likely be able to adapt to a sufficiently slow LSLR if there is space for migration. More rapid rates of LSLR may lead to changes that may hamper the successful migration of a number of organisms. If coastal LSL continues to rise, low-lying wetlands would be permanently inundated, and ecosystems in these areas would be flooded. Formerly dry land would turn into wetland. This would impact significantly the structure and function of the coastal and inland ecosystems and impact their capabilities to perform ecosystem services.

Moreover, adaptation by an ecosystem may be inhibited by processes originating outside the ecosystem. Understanding the vulnerability requires to consider ‘external’ obstacles to adaptation. Coastal development creates obstacles to ecosystems as they are trying to adapt to changes in the environmental conditions. For example, along the coasts of Denmark, Germany, and The Netherlands, dikes built to protect the land against storm surges increasingly narrow the mud-flats in the Watt and hinder ecosystems to move further inland. The increase of storm surge heights of up to 1 m predicted for most of these coast by Schwerzmann and Mehlorn (2009) and others will likely lead to more flood protections. In combination with a possible LSLR, this prediction-based adaptation would lead to a significant reduction of the unique Watt ecosystems.

In many coastal areas, wetlands and mangrove forests act as buffers to storm surges and tidal waves. In Bangladesh and Thailand, these natural coastal protections are already submerged by rising sea-levels. Normally, the mangroves would re-establish themselves at the new low-tide zone, and wetlands would migrate inland. However, in large parts of these coasts, buildings and other types of development on the coast are blocking them. As a result, interaction of LSLR and coastal protection causes a reduction of the valuable ecosystems.

LSLR is one of the greatest challenges for mangrove ecosystems (McLeod and Salm 2006). If LSLR is slow enough, then mangroves can adapt if adequate expansion space exists, and if other environmental conditions are met. If LSL is rising, the seaward and landward margins of the mangrove would have to migrate landward in order to maintain the preferred environmental conditions (period, frequency, and depth of inundation and salinity). Whether or not such a migration is successful or even possible depends on the rate of LSLR, the slope of adjacent land, sediment composition of the upland habitat, and the absence of obstacles (seawalls and other shoreline protection structures) to landward migration. In some locations, the lateral extent of mangrove would narrow down or the LSLR would lead to complete removal. What rates of LSLR would exceed the capabilities of mangroves to adapt? The answer depends on the location, but several studies indicate that in some locations $LSLR_{100}$ values of 0.12 m per century would be too much (Ellison and Stoddart 1991), while in other locations mangroves have adapted to rates of 0.25 m per century. However, we have no indication that mangroves would be able to adopt to $LSLR_{100}$ values of 0.5 m per century or more.

LSLR also would add to the stress on wild fish stocks by narrowing down crucial areas for juvenile and adult stages of many economically important marine fish and shellfish species. This would add to increasing stress due to ocean acidification, which weakens the ability of shellfish, corals, and marine phytoplankton to form their skeletons, increasing nutrient loads and pollution.

Healthy coral reefs could likely keep up with a moderate LSLR, but many reefs are already severely degraded by the effects of coral bleaching, UV-B radiation, pollution, and ocean acidification. Future increases of sea surface temperature will very likely increase stress on coral reefs, reducing their ability to compensate for LSLR.

There is a high risk that the combined stress of anthropogenic activities, climate effects, and LSLR could lead to the crossing of certain thresholds and a dramatic loss of biodiversity and degradation of services from marine and coastal ecosystems. As discussed in Section 4.14.3.2, the rates of changes in critical Earth system parameters are far outside rates experienced in the past, and coastal ecosystems might not be resilient with respect to these unprecedented disturbances.

4.14.6 Risk Assessments

As stated in Section 4.14.2, we define risk as probability, times vulnerability of assets, and times value of exposed assets. For the probability of LSLR, we have established in Section 4.14.3.2 that it is possible that for many locations (see **Figure 3**), twenty-first century LSLR_{100} could exceed 0.5 m. There is a moderate probability that many locations could experience far more extreme LSLR_{100} values in excess of 1 m. If the main contribution to a rapid rise would come from increased melting of both the GIS and the AIS, then low-latitude LSLR would be largest, while LSLR in many polar regions would be negative (e.g., sea-level would fall). If only one of the two ice sheets would have a large contribution, then sea-level would fall in the near-field of this ice sheet, and rise more than average in the opposite polar region. However, mangroves and coral reefs in the tropics and sub-tropics likely would experience a rapid rise. We also concluded that the possibility of a catastrophic LSLR of more than 2 m per century cannot be excluded for many regions particularly at low latitudes.

In Section 4.14.4 The Assets: Coastal Ecosystems and Their Services, we have underlined the high ecological, social, and economic value of coastal ecosystems. Taking the economic value alone, the estimated value of the services of coastal ecosystems is on the order of $1.6 trillion per year (Costanza et al. 1997).

The vulnerability discussion in Section 4.14.5 indicated that many of the coastal ecosystems are pre-stressed, while their capacity to adapt to LSLR is limited due to human interferences. In many cases, resilience to rapid LSLR is greatly reduced.

If we conservatively assume that for 20% of the coastal ecosystems a 21st LSLR_{100} of 0.5 m would cross a threshold leading to the complete loss of the ecosystem services, and if we further arbitrarily assume that such a rise has a probability of 0.8, then we are exposed to a risk of \$250 000 year^{-1}. A more detailed computation of the LSLR-related risk of ecosystems could be done using eqn [1]. However, due to the quantitative uncertainties in the location-dependent PDF of LSLR, the location-dependent vulnerability of the ecosystems (which depends on many factors) and the location-dependent service values would only allow an order of magnitude estimate. What we can say is that the possible 21st LSLR will lead to a reduction of the coastal ecosystem services exceeding \$250 Billion year^{-1} toward the end of the century.

4.14.7 Adaptation and Mitigation – Recommendations

During the last century, a common strategy for mitigation of sea-level hazards was (S3) (**Figure 10**), e.g., the 'hold-the-line' approach based on hard engineered coastal defenses. This approach likely would acerbate the impact of a rapid LSLR on ecosystems. It is therefore necessary to reconsider the mitigation-based approach and, where possible, to progress toward an adaptation-focused approach. The corresponding generic strategies are (S1), (S2), and (S5). In many locations, the 'do nothing' (S1) and 'managed realignment' (S2) strategies are those with the least costs in terms of lost ecosystem services, but highest in costs in terms of infrastructure and social impact. 'Soft intervention' (S5) could turn out to provide the most balanced approach, which is a hybrid of mitigation and adaptation.

Importantly, the planning for the adaptation strategy has to start as early as possible. By responsible land use planning, with limited development of those low-lying areas that likely will turn into future floodplains or areas that are need for migration of coastal ecosystems, we can keep strategies (S1) and (S2) viable. The underlying vision for the development of most low-lying coastal land areas should be based on the premise that eventually this land could give way to a rising sea. By carefully managing the factors that impact the ability of coastal ecosystems to migrate vertically, we can prepare for (S5).

The decision of where to apply the adaptation strategies (S1), (S2), and (S5) should be based on a detailed assessment of the coastal ecosystems, their specific service functions and value, and their resilience to rapid LSLR. These assessments should be carried out based on a widely accepted best practice. For many countries, this assessment would require capacity building in order to collect the required information and to carry out the assessments.

The uncertainty of GSLR projections and the fact that we cannot exclude a GSLR significantly larger than what current models can predict render long-term (century-scale) projections almost useless for planning. What is needed is an approach based on monitoring of the Earth system and forecasting of LSLR on decadal time scales, if such a model can even be developed (Plag et al. 2010). This would constitute an early warning system capable of detecting the onset of a rapid GSLR, e.g., by detecting an accelerated melting of one of the large ice sheets. Such a sea-level monitoring and forecasting service is comparable to a smoke-detector, which is a standard approach to identify a low-probability, high-impact event of a fire in a timely manner. Building such a service through international cooperation (comparable to the approach taken in the field of meteorology) would be of particular value for those countries where capabilities in analyzing and forecasting the relevant processes are not sufficiently developed. Capacity building for necessary in situ observations in the coastal zone should be a priority.

The value of coastal ecosystems and their conservation is often underestimated, especially in less developed countries, where high population growth and development pressure create a focus on short-term economic gains and a neglect of long-term economic necessities. A dedicated outreach is needed to better inform decision makers and the public about the value of coastal ecosystems and the extreme risk associated with the sea-level rise. There is also a need to develop new approaches to the dialog between science and society in order to allow for the development of an informed risk perception. Importantly, the currently common one-way interaction between science and practice needs to be augmented by feedback to science from the practitioners (Vogel et al. 2007).

Glossary

Adaptive capacity Species and system potential for resistance and resilience to environmental change; where resistance is the ability to resist a change in state and resilience is the ability to recover from a change in state following a perturbation.

Biological diversity (biodiversity) Complexity in biotic composition, structure, and function considered at levels of species (and their genetics), communities, ecosystems, landscapes, and broader scales.

Microevolution Evolutionary change (change in gene frequency over generations) within a species or its populations.

Rapid climate change In the context of this chapter, all features of local and regional surface climate whose attributes may plausibly vary over decadal through centennial scales at rates disruptive to the ecology of species and their physical and biotic environments.

Vulnerability System or species sensitivity to an environmental change relative to level of exposure to that threat.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00437-8

4.15.1 Introduction

Over recent decades, conservation biologists and land stewards have become increasingly aware of the need to incorporate rapid changes in climate as a threat to biological diversity ('biodiversity') in planning and management (Comer et al. 2012; Game et al. 2010; Glick et al. 2011; Hannah et al. 2002a; Hansen et al. 2003; Joyce et al. 2009; Mawdsley et al. 2009; National Park Service 2010). This need has intensified as we better understand the multidimensional vulnerability of the biosphere to this and other threats (Rosenzweig et al. 2007; Walther et al. 2002) and the societal consequences of biodiversity loss to ecosystem services (Chapin et al. 2000; Fischlin et al. 2007). Simultaneously, we better appreciate the large uncertainties in foreseeing future states of species and their landscapes and corresponding difficulties in incorporating vulnerability to changing climatic conditions in natural resource management plans (Kittel et al. 2011c; Lawler et al. 2010).

The chapter starts by presenting generalized outlooks for and uncertainties in climatic and biotic futures to provide context for discussions in subsequent sections (see Section 4.15.2). The core of the chapter is a review of key aspects of the vulnerability of biodiversity to climate change, considered from species – and their genetics – through community and ecosystem dynamics (see Section 4.15.3). My thesis is that this vulnerability is highly complex – running through all levels of biodiversity – and arises from ecological and evolutionary processes that are strongly interactive, span a wide range of temporal and spatial scales, and are context dependent. Inherent limitations in predicting outcomes of such complex dynamics, coupled with uncertainties in future forcings, make it difficult at best to anticipate specific consequences of this vulnerability. The chapter concludes by presenting strategies for handling such uncertainty in conservation planning (see Section 4.15.4).

4.15.2 Outlooks for Future Environments

4.15.2.1 Future Climate: Outlooks and Uncertainty

The vulnerability of species or ecosystems can be considered in terms of resistance (to changing state) and resilience (ability to recover) to changing climatic conditions and so are relative to the magnitude of the threat. In this regard, I refer to 'rapid climate change' as meaning all features of local and regional surface climate whose attributes may plausibly vary over decadal through centennial scales at rates disruptive to the ecology of species and their physical and biotic environments. An assessment of the vulnerability of current biodiversity to such variation will only be useful to the extent we can specify what the spectrum of plausible future climates might be. For this, we can look to three approaches: historical shifts, model sensitivity, and novel possibilities. The bottom line is that these approaches provide key insights and yet have high uncertainty associated with their spatial and temporal outlooks.

4.15.2.1.1 Historical Understanding

Forward-looking biotic assessments can draw from analyses of historic periods with rapid climate shifts, such as multidecadal climatic (and linked ecological) regime changes (e.g., the Pacific Decadal Oscillation; Mantua et al. 1997; Pederson et al. 2006). Such an analog approach asks what would be the status of biodiversity if regional climates were to undergo shifts today similar to those observed over past periods, and looks from this point forward, placing these changes in the context of additional threats such as invasive species, exploitation, and habitat degradation.

The primary advantage of the historical approach is that it provides an observation-based assessment of biotic sensitivity to a known forcing. A key limitation is that the past is an imperfect analog of the future – that is, future changes will likely differ in magnitude and character from those in historical or paleo records.

4.15.2.1.2 Guarded Lessons from Modeling

We can glean overarching lessons from climate model sensitivity studies, such as under scenarios of increasing greenhouse gases, sulfate aerosols, and land cover change (e.g., Avila et al. 2012; Feddema et al. 2005; Meehl et al. 2007). Caution is needed, however, in extracting these lessons because of high uncertainty associated with model projections. By 'high,' I mean where the uncertainty is as great as or greater than system sensitivity. This uncertainty is derived from:

- Climate system complexity limiting our ability to model climate (Knutti 2008; Rial et al. 2004).
- Uncertainty in future human forcings on climate such as those determined for various future demographic, economic, and political scenarios (as illustrated by the breadth of possible societal futures in Forster et al. (2007)).
- Limited inclusion of the full complement of human forcings in most climate model experiments (which usually emphasize greenhouse-gas and aerosol forcing) (National Research Council 2005; Pielke 2005, 2008).

Climate model experiments, nonetheless, convey a fundamental lesson: climate system sensitivity to a host of current and potential future anthropogenic forcings is of a magnitude and rate to raise the prospect for substantial ecological impacts with consequences for the conservation of biodiversity. While we cannot with any certainty anticipate geographic details regarding the sign or size of these effects, the very character of regional climates may likely be altered over the next decades in some generalizable but crucial ways. These entail:

- Multivariate change – including in, but not restricted to, surface temperature and precipitation. Cloud cover (and light regime), wind regime, and other parameters would be expected to change concurrent with temperature and precipitation; however, regional correlations among these variables might not hold as climate patterns shift. Minimum and maximum temperatures would also likely show different responses, as they are partly controlled by different night and daytime processes.
- Changes over a spectrum of ecological timescales – that is, changes not only in annual means but also in extremes, seasonality, and interannual variability, such as those associated with El Niño-Southern Oscillation (ENSO; Meehl et al. 2007).
- Changes shifting over time – for example, trends are not likely to be monotonic if circulation patterns shift in and out of a region or if the climate system passes thresholds or potentially irreversible 'tipping points' (Overpeck and Webb 2000; Schellnhuber 2009).

These plausible changes are of a magnitude and nature to jeopardize the persistence of species, structure of biological communities and food webs, and functioning of ecosystems (Fischlin et al. 2007; Kundzewicz et al. 2007).

4.15.2.1.3 *Novel Climates*

Changes in so many aspects of climate suggest the possible formation of novel climates, that is, climates with combinations of conditions with no current analog (Williams and Jackson 2007). The prospect that current environmental niches would disappear and new reconfigured ones arise places a caveat on our reliance on previously observed relationships of climatic controls over species and ecosystem dynamics. This outlook challenges us to contemplate future states beyond those experienced or expected, including less probable but still plausible futures (Peterson et al. 2003; Turner et al. 2003).

4.15.2.2 Climatic Vulnerability of the Physical Environment

In addition to direct effects of climate on organisms, changes in climatic conditions could modify physical components of aquatic and terrestrial environments, with indirect consequences for species and ecosystems (Figure 1, upper left panel). Changing regional and local climates could alter landforms, drainage patterns, soil development, physical and chemical attributes of aquatic systems, and physical disturbance regimes – rearranging or opening up new habitats. Key geophysical processes include:

- Modified surface-water and groundwater hydrology. In winter-snow environments, for example, reduced snowpack and earlier spring snowmelt from warming can result in seasonal shifts in riverine hydrographs (Stewart et al. 2005), affecting biologically important river, wetland, and lake conditions (e.g., water level, temperature, nutrient and sediment load, and dissolved oxygen) (Poiani and Johnson 1991; Strayer and Dudgeon 2010).
- Shifting atmospheric circulation patterns – altering ocean and lake circulation, sea ice flows, and aeolian transport (of nutrients, propagules, etc). Ocean and lake circulation changes can in turn modify the horizontal distribution of plankton (including larvae) and, coupled with altered surface heat fluxes (e.g., from warmer air temperatures), affect thermal stratification and vertical mixing of nutrients. Such horizontal and vertical structural shifts have the potential to alter marine and lacustrine food webs (Brander 2007; Harley et al. 2006).
- Altered geomorphology – from climate-forced catastrophic and cumulative processes. The former include slope instability and flooding arising, for example, from increases in

Figure 1 Determinants and consequences of species vulnerability. The figure is broadly organized into domains of stressors (climate and other anthropogenic environmental changes, *top left panel*), species-level vulnerability factors (which limit or support a species' adaptive capacity, *middle panels*), and outcomes. Factors that set a species' vulnerability are its current adaptive capacity (*middle left panel*) and microevolutionary shifts in this capacity (*middle right panel*). Outcomes of these vulnerabilities include species persistence and range changes (*bottom panel*), altered landscape and regional ecological heterogeneity (*top right panel*), and changes to genetic diversity, community structure, and the complexity of ecosystem interactions – all of which are elements of biodiversity (double-bordered boxes). Selected factors (bulleted items) give examples for factor categories, and factor linkages and feedbacks (narrow-lined arrows) illustrate interactions; not all possible factors and linkages are shown. With respect to local and regional/landscape community structure, symbols α, β, and γ refer to Whittaker's (1960) levels of species diversity, where $\alpha =$ site (sample) species diversity, $\gamma =$ regional total diversity, and $\beta =$ among-sample heterogeneity in species diversity across the region.

storm frequency and intensity or from rapid deglaciation due to warming – with effects on upland and channel or shore geomorphology (Evans and Clague 1994; National Research Council 2010). Cumulative processes include water and aeolian erosion and deposition, whose changes result in shifting landscape patterns of aggrading and degrading soils and sediments – altering drainage networks, soil structure (creating Entisols and buried horizons, for example), and water quality (e.g., from high sediment loads) (National Research Council 2010; Soil and Water Conservation Society 2003).

- A shift in ice-dominated environments to a net thaw regime. Periglacial landscapes are an example of geomorphological surfaces that are highly sensitive to climate. As complexes of thermokarst terrain with permafrost soils and thaw lakes, these landforms exhibit both stabilizing and destabilizing interactions under increasing temperatures. Their fate depends on positive and negative feedbacks among (1) temperature change, (2) changing snowpack and vegetation (and their interaction), affecting their insulation of the soil surface, (3) soil erodibility, and (4) drainage (Kittel et al. 2011b; van Cleve et al. 1991). With respect to drainage, for example, slope inclination largely determines whether permafrost degradation under warming results in an expansion of wetlands and thaw lakes (from ground subsidence on low slopes) or in wetland loss and drying soils (from drainage on steeper slopes no longer impeded by impermeable permafrost) (Rouse et al. 1997). In glacial environments, increased melting of glacial ice with warming alters downstream chemistry, such as through enhanced weathering rates due to increased meltwater contact with subglacial rock and, with receding glacial cover, altered microbial (biogeochemical) processes in newly exposed sediments (Baron et al. 2009).
- Other climate-dependent physical disturbance mechanisms – such as changes in frequency and intensity of forest windthrow and 'fire-climate' conditions leading to wildland fires, affecting ecological disturbance regimes (O'Donnell et al. 2011; Schlyter et al. 2006).

Such physical perturbations may force wholesale changes to biotic communities and their landscape patterns (Figure 1, upper panels), facilitating rapid shifts in communities that might otherwise persist under changing local and regional climates.

4.15.2.3 Future Outlooks: Biotic Consequences

We can take key lessons about biodiversity's vulnerability to plausible future climate changes from field, laboratory, remote sensing, and modeling studies (Botkin et al. 2007; Chapin et al. 2000; Rosenzweig et al. 2007; Walther 2010). As with climate outlooks, we cannot foresee the details – timing, distribution, or nature – of future ecological outcomes with any certainty. This uncertainty similarly arises from (1) ecological system complexity limiting predictability, (2) uncertainty in future climatic forcing and feedbacks, and (3) limited accounting for synergisms with other environmental stressors in climate impact assessments.

Nonetheless, in the context of generalizations about near-future regional climates previously presented (see Section 2.01.2 and Section 2.01.3 Vulnerabilities), we can derive similar generalizations from observations and models about how biodiversity might be altered over the next decades. In broad but significant ways, these include the following:

- Shifting geographic ranges of marine, continental-water, and terrestrial species (Harley et al. 2006).
- Altered species phenologies (Root et al. 2005; Wolkovich et al. 2012).
- Species interactions spatially and temporally out of phase – altering food webs, competitive interactions, and mutual associations (e.g., pollination) (Both et al. 2009; Jha et al. 2013).
- Changing community structure – potentially giving rise to novel ecosystem types (Overpeck et al. 1992; Seastedt et al. 2008; Urban et al. 2012).
- Changes in ecosystem function – altering biophysical and biogeochemical processes, including primary production (Nemani 2003).
- Disruption of ecosystem services – affecting societal use of resources as water, food, etc. (Cardinale et al. 2012; Chan et al. 2011; Fischlin et al. 2007).

Temporal behavior of these ecological responses will generally follow not only from climatic (and other) forcing, but also from internal stabilizing or nonequilibrium dynamics. The result being:

- A new equilibrium, inasmuch as such has existed historically, would be long in coming, pending first climatic and then ecological stabilization (e.g., at centennial scales) – resulting in extended periods dominated by seral stages.
- Following from shifting climate regimes, ecological changes would not be monotonic – with no single specific outcome developing and persisting over the long term (e.g., no 'winner' or 'loser' species).
- Internal dynamics would exhibit system lags, regime shifts, and tipping points (Allen and Holling 2010; Biggs et al. 2009; Jones et al. 2009; Metzger et al. 2009).

These potential outcomes arise from the fundamental nature of biodiversity and its climatic vulnerability. Processes and factors controlling this vulnerability are explored next.

4.15.3 Nature of Biotic Vulnerability

4.15.3.1 Vulnerability across the Biodiversity Hierarchy

Biodiversity broadly includes complexity across levels of biotic organization from genetics and populations to communities, landscapes, and ecoregions (and so on). Within these levels, biodiversity also includes complexity with respect to composition (elements present), structure (arrangement of elements), and function (interactions among elements) (Noss 1990). The structure and function of genetic through ecoregional diversity contribute to the maintenance of species diversity and are themselves established as important conservation goals (Groves et al. 2002). Biodiversity is vulnerable to climate across this hierarchy in complex and highly interactive ways (Fischlin et al. 2007; Walther et al. 2002). This section starts with a species-level approach to climate vulnerability, focusing on a species' adaptive capacity and its links to genetic diversity, and then discusses community and ecosystem vulnerability, landscape connectivity, and synergisms with other threats.

4.15.3.2 Species Adaptive Capacity

4.15.3.2.1 Species Ecology

Physiological Range

A species' adaptive capacity – that is, the potential for resistance and resilience to environmental change – arises from flexibility in its ecological relationships (**Figure 1**, middle left panel). On first consideration, such flexibility with respect to climate is tied to the breadth and shape of physiological response curves – such as with respect to interacting thermal, moisture, light, chemical (nutrients, salinity), and other climate-linked environmental conditions. Broad physiological optima will support species resistance; while species with narrow physiological limits are subject to catastrophic responses (e.g., tropical organisms with little freeze tolerance). (The genetics of broad versus narrow climatic optima is discussed later on.) In addition, physiological tolerances change with life stage in many species (Harley et al. 2006), so that vulnerability may be linked to a critical time or may shift among factors during an organism's lifespan.

Species Interactions

The link between a species' adaptive capacity and physiology may, however, be muddled by interactions with associated species, including competitors, predators, prey, mutualists, and pathogens (**Figure 1**). Consequently, species vulnerability may be just as much indirectly determined via climate responses of associates (and so by altered community compositional and structural diversity) as by direct forcing of a changing climate. The impact of community restructuring (discussed later) on a species' vulnerability propagates in through trophic and other ecological networks – that is, from beyond the species' most immediate connections. Altered interspecific interactions can ameliorate a species' vulnerability, such as through competitive release, or exacerbate it as from reduced resource availability. Species with high adaptive capacity:

- Can readily shift resource utilization under shifting competitive and trophic environments.
- Are not highly dependent on mutualistic relationships (or at least not with species lacking matched adaptive capacity) (Hughes et al. 2003; Jha et al. 2012).
- Have resistance (expressed or latent) to emergent diseases.

Population Viability

Population dynamics also determine species vulnerability (**Figure 1**). Direct climatic impacts on reproduction and mortality rates alter population viability across a range of timescales (e.g., from hourly events to decadal variability). Such controls over population size are manifested as both density-independent climate effects (as from catastrophic events) and density-dependent effects (where the climate impact depends on, for example, the magnitude of intraspecific competition for food, shelter, and mates). At weekly scales, for example, changes in frequency and timing of severe winter storms can have both density-independent and dependent effects on large mammal survivorship (Berger 1983; Hallett et al. 2004).

Both animals and plants exhibit climate-induced shifts in reproductive traits affecting population dynamics, such as fecundity, generation time, breeding/flowering season, and other phenological traits (Inouye 2008; Isaac 2009; Post et al. 2001). How traits respond to climate and the consequences for population viability depend on a species' overall life-history strategy – such as for r- versus K-selected species, generalists versus specialists, and for different mating systems; in these contrasts, similar climatic behavior can generate opposite outcomes (Isaac 2009).

Population viability is also tied to species interactions, as those discussed above. At seasonal scales, reproduction and survivorship are altered by loss of phenological synchrony between:

- A species' climate-cued life-history events and climate-cued trophic resource availability, as seen in migratory and winter-dormant vertebrates (Both et al. 2009; Forchhammer and Post 2004; Harrington et al. 1999; Inouye et al. 2000).
- The climate-cued life-history events of mutualists, as for plants and their pollinators (Jha et al. 2012).

At interannual and longer scales, climate affects predator-prey population cycles – such as that involving Canadian lynx and snowshoe hare (Stenseth 2007) – and climate-regulated host-disease dynamics, as in insect herbivore-parasitoid systems (Hance et al. 2007; Stireman et al. 2005) and plant host–pathogen interactions (Brasier and Scott 1994; Woods et al. 2005).

The constraints imposed on adaptive capacity by intra- and interspecific interactions tend to narrow a species' range relative to its potential climatic limits based on physiology alone. If changing population and community dynamics shift these constraints, a species may reveal latent capacity to fill niches that are consistent with its physiological limits but from where it has been excluded.

4.15.3.2.2 Dispersal Capacity and Range Shifts

Vulnerability also depends on a species' ability to disperse away from sites becoming less favorable to improving ones – that is, to successfully track suitable conditions as they shift across a landscape or region (**Figure 1**, middle left panel). While the potential for species range shifts is often evaluated with empirical 'climate envelop' or environmental niche models, dispersal success is tied to dispersal life-history strategies and interspecific interactions generally not incorporated in these models (Davis et al. 1998; Wiens et al. 2009; however, see Anderson et al. 2002 and Keith et al. 2008).

Even within taxonomic groups, species substantially differ in dispersal attributes, setting their potential for keeping up with elevational or lateral shifts in climates (Chen et al. 2011; Urban et al. 2012). Species factors include the following:

- Capacity for diffusive or jump dispersal, whether by self-locomotion or facilitation by wind, water, or other species.
- Establishment life-history strategies (e.g., reproductive rates, competitive abilities, and adult survivorship associated with early versus late successional species).

Successful dispersal is also a function of environmental conditions along the way. Source-to-sink abiotic and biotic site factors include the following:

- A species' current distribution and population size (source strength) including persistent relict populations existing outside of its generalized climatic range (Botkin et al. 2007).
- Landscapes en route presenting physiographic or biotic barriers and corridors (including limitations or opportunities offered by human-modified domains).

- Suitability of potential sink habitats in terms of their abiotic, trophic (food resources, predator), and competitive setting (Urban et al. 2012).

Species whose in situ adaptive capacity is low – and thus vulnerable to local extirpation – and additionally are poor dispersers and isolated from emerging favorable sites by physiography or human land use are additionally vulnerable to extinction (**Figure 1**, bottom left panel). While these processes look at the leading edge of range shifts, demographic factors and reproductive traits (e.g., longevity, cloning) and disturbance tolerance are species-specific controls over lags (species persistence) at the trailing edge (Elliott-Fisk 1983; Hampe and Petit 2005).

Species differences in adaptive capacity in general and dispersal ability in particular would lead to differential rates of range movement under a shifting climate (and disturbance) regime. A resulting mixture of colonizing, lagging, and declining species will contribute to community structural disruption, the predominance of seral (successional) associations, and, potentially, to the rise of novel communities (**Figure 1**) (Urban et al. 2012; Williams and Jackson 2007). The nature and rate of community change will depend on:

- Relative 'openness' of the current community – versus one presenting a highly competitive environment.
- Climate vulnerability – and hence degree of persistence – of dominant and keystone species that maintain existing community structure.
- State-changing disturbance (fire, insect outbreaks).
- Dispersal and establishment abilities of arriving species.

Under slow rates of climatic change, communities may maintain their composition but alter their relative structure, at least in the shorter term (Breshears et al. 2008; Kelly and Goulden 2008). However, under high disturbance with rapid changes in local climate, communities may collapse, presenting open environments to arriving species. Community structural vulnerability is discussed further in Section 3.03.1 Introduction.

4.15.3.2.3 Phenotypic Plasticity

Phenotypic plasticity can shift adaptive capacity under a rapidly changing climate without relying on genetic variation (Reed et al. 2011; Rice and Emery 2003). Requirements for adaptive phenotypic plasticity are that:

- environmental cues are sufficiently reliable to trigger plastic responses,
- plastic responses sufficiently track the pace and breadth of environmental changes,
- fitness benefits exceed costs of maintaining plastic potential (Reed et al. 2011).

The degree of plasticity varies widely among taxa. For some species, adaptive plasticity is not sufficient to optimize fitness throughout a species' current climatic range (e.g., as seen for a temperate-grassland annual forb in a reciprocal transplant study, Etterson 2004b), potentially leading to reduced local population viability under a shifting climate. For others, it may be as great as to accommodate wide climatic shifts. For example, over the Pleistocene glacial–interglacial cycle, a kangaroo rat species largely maintained its current distribution by shifting its realized niche likely through phenotypic plasticity, rather than with genetic change (Jezkova et al. 2011).

4.15.3.2.4 Geographic Gradients in Adaptive Capacity

Genetic Differentiation Across a Species' Range

As the underlying basis for adaptive capacity, genetic make-up sets the vulnerability of a species to a changing environment. However, abiotic and biotic constraints on populations tend to affect a species' adaptive capacity differently at range extremes and at extremes versus in its core, applying different selective pressures and driving geographic genetic differentiation (Bentz et al. 2001; Case and Taper 2000; Davis et al. 2005; Hampe and Petit 2005; Howe et al. 2003). Consequently, physiology, life history, and other (genetic-based) elements of adaptive capacity may differ substantially for populations at the core of a species' distribution versus those at its limits. Such populations may then have different responses to similar climatic change. A species' vulnerability then varies geographically not only with varying availability of suitable habitats, but also with location-specific genetically determined capacity to adjust to new local niches (e.g., Etterson 2004a; Rehfeldt et al. 1999).

A consequence of this geography is that populations in the core of a species' range may be maladapted to its marginal climates. Such a 'core population' may not be viable under a climate shift that brings it near to, but still within, the limits of the species' current climate range. Under these conditions, empirical niche (climate envelop) models would overestimate a species' persistence.

Role of the Past

Biogeographic history (how species got to where they are now) and evolutionary history (how they changed along the way and once there) are determinants of current genetic geography. Regional climatic history plays a role in such geographic differentiation. For example, it can act to reduce local genetic diversity under diametric conditions of:

- steady climate regimes, through stabilizing selection (Rice and Emery 2003),
- rapid climate change or severe events (such as sustained drought), creating genetic bottlenecks.

In both of these cases, past conditions potentially reduce current adaptive capacity and increase local vulnerability to future climate shifts. Effects of climatic variability on genetics are discussed further in the next section.

4.15.3.2.5 Shifting Adaptive Capacity in Time: Microevolution

Direct abiotic and indirect biotic forcing associated with a changing climate apply corresponding selective pressures; the question is whether these pressures can sufficiently shift population genetics at ecological timescales to reduce species vulnerability. Microevolution, that is, evolutionary change within a species or its populations, has allowed some taxa to adapt to recent human-forced environmental change, including altered climatic conditions (reviewed in Rice and Emery 2003). This is to say that genetic shifts in populations that maintain their viability can occur at rates matching rapid environmental change. Consequently, evolutionary rates may be large enough for some species to adapt to rapidly changing local climates, reducing the probability of their extinction (Reed et al. 2011; Rice and Emery 2003).

Climatic Selective Pressures

Climate-linked selective pressure produces three generalized outcomes as a function of climatic temporal behavior (Reed et al. 2011; Rice and Emery 2003):

- Climatic consistency gives rise to stabilizing selection reducing generic diversity, in turn reducing adaptive capacity, as previously mentioned.
- Directional change in climatic conditions supports net directional selection, shifting adaptive capacity. However, rapid climate shifts exert strong selective pressure, which may exceed microevolutionary potential (discussed shortly). A consequence of strong selection is high levels of mortality. This may make even currently robust populations vulnerable by diminishing their size and condition to levels where they become subject to stochastic fluctuations in numbers and genetics (genetic drift) (Reed et al. 2011). This threat to population viability may occur even as directional selection is moving phenotypes to a new environmental optimum in the remaining population.
- If climatic variability increases in a way that gives inconsistent direction to selection pressures, it can disrupt both stabilizing and directional selection. This would lead to poor climatic optimization and reduced adaptive capacity. Alternatively, increased variability can promote selection for phenotypic plasticity, but only if the altered climate regime has a predictable element that be relied on as an environmental cue – a required condition for plasticity noted earlier. Without this predictability, however, plasticity would be less reliable and so less favored under increased climate variability (Reed et al. 2011).

Strong environmental perturbation can, in addition, trigger release of cryptic genetic variation – variation present but otherwise not phenotypically expressed (Gibson and Dworkin 2004; McGuigan and Sgrò 2009). Such a release produces novel, potentially adaptive phenotypes (Hayden et al. 2011). Suggested trigger mechanisms are through environmental disruption or genetic mutation (which itself can be induced by environmental stress, Reed et al. 2011).

Factors Controlling Microevolution

Microevolution is limited by (1) genetics, (2), reproductive biology and demographics, and (3) coevolutionary processes (Rice and Emery 2003). Genetic factors that constrain or facilitate microevolution include the following:

- Local genetic diversity, providing either a genetic source for adaptive shifts or a drag from genetic load (suboptimal genes reducing fitness).
- Metapopulation gene flow, which can provide a population with either (1) genotypes well adapted to new conditions or (2) maladapted genes more suited to the source location and so adding genetic load (i.e., antagonistic gene flow).
- Phenotypic plasticity, discussed earlier, which can buffer the negative effects of strong selective pressure and allow time for genotypes to track environmental shifts.
- Positive or negative genetic correlation among adaptive traits (which each support an optimal phenotypic response to an environmental change) can accelerate or hinder selection relative to traits that act independently. Traits that act in concert (through synergistic genetic interaction) promote adaptive change. On the other hand, with negatively correlated traits, promotion of one trait reduces selection for the other. Such antagonistic genetic interaction makes directional selection ineffective in optimizing a phenotype to a consistently changing environment (Etterson and Shaw 2001). Genetic interactions are further complicated when traits that are positively correlated under selection favoring some phenotypes are negatively correlated in selection favoring others (Snitkin and Segrè 2011).

On this last topic, positive genetic correlations may not be stable under multivariate environmental change, where selective pressure is for phenotypes to track multiple shifting optima (Reed et al. 2011). Additionally, under the development of shifting or novel climates, a breakdown of currently reliable correlations among environmental variables (such as between temperature and day-length seasonality) may disrupt current positive genetic correlations (such as among traits setting cold-season acclimation in temperate and boreal plants; Howe et al. 2003).

Microevolutionary factors related to reproductive biology and demography include the following:

- Environmentally cued shifts in sexual versus asexual reproduction in plant, animal, and microbial taxa (Chen and McDonald 1996; Elliott-Fisk 1983; Hughes et al. 2003).
- Generation time, fecundity, and population size – where short generations, many offspring per generation, and large populations contribute to higher population growth potential, facilitating adaptive evolutionary shifts (Hughes et al. 2003; Reed et al. 2011).
- Reproductive longevity of adults and viability of dormant propagule reservoirs (e.g., seed banks), which can provide either genotypes that have come around again to be well adapted or ones that increase genetic load (Hughes et al. 2003; Rice and Emery 2003).

Coevolutionary selective pressures arise from shifting trophic, mutualistic, or epidemiologic interactions. These pressures may be particularly crucial when one species' microevolutionary response is tightly constrained by the adaptive capacity of and concurrent (but not necessarily matching) evolutionary changes in coevolved associates (Holt 1990; Rice and Emery 2003).

4.15.3.3 Vulnerability of Community Structure and Ecosystem Function

4.15.3.3.1 Structure

Response of communities to a changing environment is determined not only by species' individual responses to external forcing, but also by internal dynamics. Community structural changes (composition, richness, evenness) arise from the relative strengths of forcing and species interactions. Three paths are determined by the dominance of (1) physically disruptive climate forcing, (2) weak biotic interactions, or (3) strong, system-defining biotic interactions (Figure 1, upper left panel).

In the first case, climate drives catastrophic or cumulative changes to the physical environment sufficient to disrupt the integrity of a community (as previously discussed). Primary or secondary succession will give rise to potentially novel sequences of communities under new, shifting abiotic (climate, disturbance regime) and biotic (e.g., arriving species) conditions.

Under a climate that is not so disruptive to the physical habitat, community responses to climate depend on the strength of interactions among species (Chapin et al. 2000). In communities where species belong to fairly generic functional groups and interactions are weak (that is, flexible among roughly substitutable species), community structure is affected by an overall shifting presence and abundance of species as they respond to climate and to trophic, mutualistic, and competitive interactions. In this case, communities adjust primarily 'bottom up' – progressing up trophic networks in response to, for example, changes in primary producer or microbial decomposer populations, the principal facilitators of system energy or nutrient flows (Chapin et al. 2000; Harrington et al. 1999; Inouye 2008; Mantua et al. 1997; McGowan 1998; Walther 2010).

In communities with strong interactions, on the other hand, structural changes may be determined by the presence and abundance of single species – such as for keystone taxa, whose presence or loss cascades 'top down' through trophic levels (Chapin et al. 2000; Power et al. 1996; Walther 2010). In general, such species-sensitive restructuring occurs where:

- Mutualistic, trophic, or competitive interactions are tight – e.g., for animal pollinator–plant interactions, top predators, and grazer-determined plant succession (Collins and Calabrese 2012; Jha et al. 2012).
- A species' traits strongly control system dynamics – such as for species that tightly regulate system resources, disturbance regime, or microclimate (e.g., nitrogen-fixer, low water-use efficiency, fire-prone, and permafrost-stabilizing plant species) (Chapin et al. 2000; D'Antonio and Vitousek 1992; van Cleve et al. 1991; van Wilgen et al. 1996; Wilson and Agnew 1992).

Within a food web, strong bottom-up and top-down effects may both play a role – with top-down restructuring influencing lower trophic levels and bottom-up simultaneously affecting top levels (e.g., Shurin et al. 2012), potentially in a way that can synergistically contribute to ecosystem stability (de Ruiter et al. 1995).

Emergent versus Species Responses

A straightforward community-level phenological response to shifts in seasonal climate may say little about individual species responses and the consequences for tight species interactions. For example, a lengthening of the growing season for mid- and high latitude terrestrial plant communities could be expected to increase food resources for herbivores. However, this community response is likely emergent from a variety of individual plant species responses – some advancing their phenologies, some with cycles sped up or lengthened, and others with little change (Steltzer and Post 2009). For herbivores, a consequence can be disrupted timing of plant species that provide crucial dietary needs during specific periods of the summer (e.g., in preparation for hibernation) (Hill and Florant 1999; Steltzer and Post 2009).

4.15.3.3.2 Ecosystem Function

Climate and Plant Functional Types

Terrestrial biogeochemical processes are largely controlled by moisture and thermal regimes in interaction with soil properties (e.g., water and nutrient holding capacity), vegetation, and geomorphology (e.g., hillslope position) (Band et al. 1993; Daly et al. 2000; Parton et al. 1995). The role of plant community structure and species composition can be generalized by plant functional types that categorize species' contributions to ecosystem physiology and architecture (Smith et al. 1997). Such functional distinctions affect biogeochemical rates through quantity and quality (nutrient versus structural content) of plant matter inputs inherent in contrasts of, for example, annual versus perennial herbaceous, deciduous versus evergreen woody, C_4 versus C_3 photosynthetic pathway, and nitrogen fixing versus non-fixing species. Climate-driven shifts in the diversity of an ecosystem's plant functional types, especially with the gain or loss of key types controlling system dynamics, can be major determinants of the climate response of energy and matter flow rates and pathways (Díaz and Cabido 2001; Kappelle et al. 1999). This sensitivity to shifts in key types can occur even if each type is represented by only one to a few species, resulting in little change in overall species diversity.

Aboveground–Belowground Ecosystem Interactions

Material and energy flows in terrestrial ecosystems are also determined by climate-sensitive interactions between above- and belowground realms and so by traits of these communities (Bardgett et al. 2005; Wall 2007; Wardle et al. 2004). Belowground microbial and faunal communities interact with the aboveground realm in ways that depend on the nature of their association with plants – those in food webs associated with roots (with primary consumption by root herbivores, parasites, and pathogens), in detrital food webs (decomposers), versus in mutualistic association with roots (mycorrhizae) (Bever et al. 2010; De Deyn and Van der Putten 2005; Wardle et al. 2004).

The aboveground community exerts strong control over detrital and root food webs primarily through the quantity and quality of plant matter – a function of plant community composition, as described above. In addition, aboveground herbivory can alter plant tissue quality – in the short term, through plant biochemical responses (of increased nitrogen content and/or secondary defensive compounds) and, in the long term, through plant community shifts (to lower quality forage species) (Wardle et al. 2004).

At the same time, belowground communities strongly influence plant productivity (and tissue quality) through:

- The detrital food web, both mineralizing organic inputs to available forms and competing with plants for these nutrients.
- Mycorrhizal facilitation of plant nutrient uptake.
- Degradation of root uptake efficiency by the root-associated food web (through root consumption and disease).
- Belowground microbial and invertebrate induction of plant defenses against aboveground herbivory and plant-shoot pathogens, altering plant growth and chemistry (defensive compounds). Such plant productivity and tissue chemical responses can be both plant- and belowground inducer-species specific and have bottom-up community effects, shifting plant competitive and trophic interactions (Bezemer and van Dam 2005).

Climatic vulnerability of ecosystems emerges from the compositional and functional diversity of these communities and complexity of their interactions (Chapin et al. 2000; Kappelle et al. 1999; Wardle et al. 2004). Biogeochemical processes and functional group behavior are strongly sensitive to their climatic controls; however, ecosystem model intercomparison studies suggest high uncertainty in our understanding of this vulnerability even at the broadest (regional and continental) scales (Cramer et al. 2001; Purves and Pacala 2008; Schimel et al. 2000). At finer scales, the magnitude and expression of climate vulnerability are even less predictable because above- and belowground dynamics are highly nonlinear and depend on site details, such as soil fertility and, as just described, soil and plant community composition and aboveground herbivory (Wardle et al. 2004). Such nonlinear ecological networks are potentially capable of sudden regime shifts and passing through tipping points in their structure and function (Biggs et al. 2009; Hastings and Wysham 2010; Wall 2007).

4.15.3.4 Landscape–Global Continuum

The spatial arrangement of communities and ecosystem processes on the landscape brings additional complexity arising from physical and biotic connectivity. Connectivity of landscape units provides for water- and air-mediated flow of energy and materials (e.g., organic and inorganic particles, water, and propagules) downslope and downwind (Reiners and Driese 2001; Seastedt et al. 2004; Soranno et al. 1999). In addition, landscape continuity facilitates seasonal and ontogenetic (life-stage) migrations and range expansion (Berger 2004; Olds et al. 2012). Such biogeochemical, population, and other linkages are vulnerable to disruption of the physical environment (e.g., shifted hydrology and destabilized landforms, as discussed earlier) and interruption of biotic continuity through rearrangement or loss of crucial communities (such as suitable habitats forming corridors or those that are key sources for transported organic material).

Connectivity extends to regional and global scales with interbasin, intercontinental, and between ocean and continent aeolian transport of aerosols (e.g., nitrogen deposition), dust (from aridlands), and organisms (e.g., microbes, insects, propagules) (Baron et al. 2009; Brander 2007; Sharma et al. 2007; Washington et al. 2009; White et al. 2012). Sustained changes in such inputs can alter ecosystem function and structure (Avila and Peñuelas 1999; Fenn et al. 2003; Steltzer et al. 2009).

4.15.3.5 Synergisms among Climate and Other Stressors

Climatic impacts on species adaptive capacity are, in addition, in the context of other environmental stressors on biodiversity (Figure 1, upper left panel). These include direct anthropogenic effects such as habitat conversion (e.g., Vieira et al. 2009), exotic invasive introductions ('biotic homogenization,' Olden et al. 2004), and disruption of biogeochemical cycles (Vitousek et al. 1997). Acting together, these stressors exhibit not only additive effects but also strong synergisms with climate (Brook et al. 2008). Exacerbating feedbacks between climate and other stressors include those with:

- Habitat modification – including (1) atmosphere-land surface feedbacks accompanying land use change, such as fragmentation, salinization, and desertification (e.g., accelerated drought with deforestation; Laurance and Williamson 2001) and (2), for aquatic environments, compounding influences of precipitation regime change, upland land use, and water impoundment on light, temperature, sediment load, and chemistry of continental and coastal waters (Walling 2009).
- Overexploitation of species utilized for food, timber, etc. where reduction or extirpation of populations and disruption of food web dynamics increase a species' vulnerability to other stressors (such as climate) (Biggs et al. 2009; Brander 2007; Nellemann et al. 2008).
- Altered fire disturbance regime – from environmental changes including (1) human-related fire suppression or ignition, (2) shifts to more fire-prone plant communities with the establishment of invasive exotics, and (3) fertilization from atmospheric nitrogen deposition adding fuel load (D'Antonio and Vitousek 1992; Fenn et al. 2003; Schoennagel et al. 2004).
- Altered chemical environment – inducing biogeochemical and community changes from (1) elevated atmospheric CO_2-induced fertilization (of terrestrial plants) and ocean acidification (to the detriment of calcifying marine organisms), (2) introduced toxins via air, soil, and water pollution, (3) atmospheric deposition causing soil and water acidification and enhancing nitrogen inputs (as just noted regarding fire), and (4) altered terrestrial nutrient runoff to continental waters and oceans (Baron et al. 2009; Brander 2007; Fenn et al. 2003; Gitay et al. 2001; Kleypas et al. 1999; Pandolfi et al. 2011). In terrestrial and aquatic systems, changes in physical climate influence these chemical deposition, infiltration, and runoff impacts (1) directly through shifting precipitation and snowmelt regimes and (2) synergistically, with thermal and moisture regimes also affecting these biogeochemical responses.
- Insect outbreaks – aided by climate directly through (1) altered host plant susceptibility (e.g., plant moisture status) and (2) altered insect life cycles (e.g., a step-up in the number of breeding cycles per annum) (Mitton and Ferrenberg 2012; Raffa et al. 2008).
- Invasive exotics – with climate-facilitated spread of invasives through, for example, new establishment opportunities arising from shifts in (1) dispersal routes (via wind and water circulation), (2) disturbance regimes, or (3) competitive setting (from community shifts) (Burgiel and Muir 2010; Hellmann et al. 2008). In a climatic feedback, the impact of invasives on community structure can be strong enough to alter basin microclimates and hydrology (van Wilgen et al. 1996).
- Disease invasion – where the introduction and spread of emergent diseases into wildland plant and animal communities are driven by an array of factors acting individually and synergistically. These include: (1) land use change encroaching on natural areas, such as land conversion for agriculture, settlement, and water impoundment (giving rise, for example, to zoonoses – animal diseases transmitted through contact of wildlife with domestic animals and humans; Patz et al. 2000), (2) atmospheric N deposition and elevated atmospheric CO_2 (e.g., affecting susceptibility to disease due to altered plant growth patterns; Mitchell et al. 2003), (3) diminished plant community diversity resulting in increased host-species

densities (e.g., directly through management or indirectly through plant preferences of introduced grazers; Borer et al. 2009), and (4) changing climatic conditions (Crowl et al. 2008; Patz et al. 2000; Woods et al. 2005). Introduction of new diseases and elevated infection rates significantly impact the structure and function of ecosystems (Anderson and May 1986; Crowl et al. 2008), with the outcome determined in interaction with climate and other stressors.

Such a multiple-stressor context provides for a more encompassing assessment of climate vulnerability, yet with concomitant levels of added uncertainty (Sala et al. 2000).

4.15.4 Implications for Biodiversity Conservation: Fundamentals, Uncertainties, and Planning

4.15.4.1 Fundamentals of Vulnerability

Fundamental lessons that emerge regarding the vulnerability of biodiversity to climate are:

- Biodiversity at species through landscape levels is vulnerable to climate acting (1) directly on organisms – which, through ecological networks, generate and are subject to higher-order population, community, and ecosystem vulnerabilities, (2) indirectly through climatic alteration of the physical environment, and (3) synergistically with other stressors.
- At the species level, adaptive capacity – countering such vulnerability – arises from (1) physiological breadth, (2) life-history strategies affecting population viability, (3) flexibility of interspecific (mutualistic, competitive, and trophic) interactions, and (4) dispersal capable of tracking shifting favorable conditions elevationally and laterally.
- Species adaptive capacity is mutable through (1) phenotypic plasticity and (2) microevolution – both highly variable among species as a function of genetic, reproductive, and coevolutionary controls. Some elements of adaptive capacity are latent – potentially released by changing conditions (such as release from competition and triggering of cryptic genetic variation).
- Genetic basis of adaptive capacity geographically varies over a species range as a consequence of (1) variation in microevolutionary potential, (2) abiotic and biotic environmental gradients affecting selective pressure, and (3) climatic and evolutionary history.
- Vulnerability of communities and ecosystem material and energy flows emerges from (1) community composition, especially as it relates to the functional diversity of species (i.e., in terms of general functional types and species with system-determining traits), (2) complexity and strength of interactions, especially the extent to which trophic network structure is determined by bottom-up and/or top-down interactions, and (3) matter and energy exchange among landscape units (and with domains farther afield).
- In all these aspects, vulnerability is context dependent, for example, what (what species, with what genetics, and in what community networks), where (in the core versus margin of its geographic range, and in what current climatic, physiographic, and ecological region), and when (what history, what foreseeable future threats).

4.15.4.2 Uncertainties

These vulnerabilities involve complex interactions among multiple system components and across a broad range of time and space scales. This complexity results in nonlinear dynamics, as previously noted, potentially exhibiting lagged (Jones et al. 2009; Metzger et al. 2009) and threshold (regime-shift or tipping-point) behavior (Barnosky et al. 2012; Biggs et al. 2009; Burkett et al. 2005; Malhi et al. 2009). Such systems are inherently difficult to predict (Hastings and Wysham 2010; Holt 1990; Scheffer et al. 2009; Wardle et al. 2004), affecting our ability to assess species and system vulnerability.

Given that vulnerability is judged relative to the magnitude and nature of stressors, such assessment is also hampered by uncertainty in drivers of change – whether climatic or from other threats, as previously discussed. Predictability is additionally constrained by our limited understanding of even modest portions of vulnerability dynamics summarized in the previous section (and in Figure 1) – especially when focused on a species or community of concern, much less for whole landscapes. One source for this deficiency is insufficient observations of systems under rapid, multisource environmental change that would reveal key dynamics – such as, to name but a few:

- Latent adaptive capacity of species such – as phenotypic plasticity, microevolution, and cryptic genetic variation
- Co-microevolutionary potential of mutualists (e.g., Rice and Emery 2003)
- Cross-temporal and spatial scale population responses to climate variability (e.g., Hallett et al. 2004; Stenseth and Mysterud 2005)
- Role of interspecific competition during species range movement (Davis et al. 1998)
- Threshold versus system-stabilizing community dynamics (e.g., de Ruiter et al. 1995)
- Dynamics leading to the rise of novel ecosystems (Williams and Jackson 2007).

In sum,

- Biodiversity is vulnerable to changing climate conditions across its breadth and depth – that is to say, altering composition, structure, and function of species genetics and populations and communities, ecosystems, and landscapes. Vulnerability is highly interwoven across these levels and across temporal and spatial scales, as well as being context dependent.
- Uncertainty in the outcomes of this vulnerability, however, is high—that is, potentially equal to or greater than the magnitude of the vulnerability.

The bottom line is that the task of incorporating climate vulnerability into conservation planning is both essential and inherently difficult.

4.15.4.3 Dealing with Climate Uncertainty in Conservation Planning

While plausible future changes in climate put at risk species persistence and the integrity of community networks and ecosystem function, uncertainty in how this will be played out means we are far from being able to adequately assess ‘on the ground’ outcomes of this vulnerability. Such uncertainty can be perceived as overwhelming, blocking progress toward including climate vulnerability in conservation planning. To overcome this roadblock, a strategy is needed to deal with uncertainty in an appropriate way – that is, a strategy that explores and copes with uncertainty, rather than putting it aside.

There are many areas in our professional and personal lives where we undertake strategic planning in the context of uncertain future conditions; nonetheless, we face these uncertainties and devise and implement plans according to our expertise and information available. Conservation planning by its nature deals with threats that have highly unpredictable elements such as habitat fragmentation, invasive species, or altered disturbance regime. We may not know, for example, the timing, duration, intensity, location, or other critical attributes of a threat, yet conservation teams devise management plans to address these threats (Groves 2003).

We can also look for guidance for planning under uncertainty in disciplines farther afield. Uncertainty in financial markets has similarities with that in ecological systems (Scheffer et al. 2009). In both cases, high uncertainty arises from:

- Low predictability due to system complexity – e.g., from nonlinear, positive and negative feedback, threshold, and cross-scale (micro- to macroeconomic, genetic to ecosystem) dynamics.
- Poorly understood (and poorly quantified) system-wide behavior or behavior of even limited domains (i.e., economic sectors, 'vulnerability domains' in **Figure 1**).
- Unknown, or not widely recognized, intrinsic and extrinsic threats to system stability.

We can then borrow basic tenets from financial planning for a scheme for conservation planning under an uncertain climate future. In analogy to 'to invest smart,' 'to conserve smart' is to implement strategies that recognize and handle uncertainty – that hedge against worst-case scenarios, but which do not lead to poor decisions under current conditions. I paraphrase six investment 'coping with uncertainty' tenets which contribute to an integrated conservation strategy for climate change (presented in Section 4.15.4.4). (Quoted investment lessons are not from specific sources, but, rather, are common guidance found, for example, on the Internet.)

4.15.4.3.1 Tenet 1: Monitoring and Historical Analysis

Monitoring temporal dynamics and long-term trends develops a knowledge base and intuition of system dynamics influencing biodiversity on which to base and modify decisions (analogous to "Never invest in something you don't understand"). An early emphasis on monitoring, if not already ongoing, builds an observational dataset that can be the basis for historical analyses and model development. Initiating monitoring at the onset – not after the planning process is completed nor as an afterthought to monitor a plan's effectiveness – has the benefit of providing the longest possible record. A longer observational record increases the chance of capturing dynamics counter to or more complex than our expectations (e.g., shifting or unstable behavior). Care should be taken in designing and implementing a monitoring program to assure that the record is free from inhomogeneities and other data quality issues so it may be relied on for temporal analyses (Kittel 2009).

Analysis of long-term records lends valuable insights to the question of vulnerability and with it a first-order estimate of future behavior. However, this tenet comes with a caution regarding extrapolation that future dynamics may well go outside of what has been observed in the past ("Past performance is no indication of future return").

4.15.4.3.2 Tenet 2: Diversify Holdings

A common conservation planning strategy for identifying critical locations for protective measures is to select a portfolio of best sites possible – sites with, for example, (1) the largest populations of a species or the greatest extent of an ecosystem of interest, (2) the best quality of habitat, and (3) the lowest level of threats, current or foreseeable (such as areas with substantial buffer zones – e.g., buffered from roads and other human development). These 'best of the best' criteria assist in selecting conservation sites with the most intact processes supporting biodiversity and ecological and evolutionary function.

Achieving diversity among such sites in terms of their key attributes is a complementary strategy to reduce risk to biodiversity under high environmental uncertainty ("Diversify your portfolio to reduce risk"). Selecting multiple sites under best-site criteria for multiple conservation elements (species and ecosystems) will diversify holdings as a matter of course, with sites selected to optimize criteria in different ways for different elements. However, as in investing, site diversification can adhere to yet higher standards – a diversity of sites meeting best-condition criteria may be akin to a portfolio of highly rated stock diversified across sectors; focused on stock, it has higher risk relative to one diversified with additional instruments as bonds, real estate, and commodities ("Similarity among holdings reduces a portfolio's effective diversification"). Concepts (and tools) regarding financial portfolio optimization can be employed to design and evaluate diversification in conservation plans (Ando and Hannah 2011; Moore et al. 2010).

An additional strategy to enhance diversity in site selection is to recognize opportunities to support adaptive capacity in otherwise passed-over sites. For example, low priority sites – whether an occurrence of a currently small, unviable population or a marginal habitat – may have greater value in light of climatic uncertainty if they harbor critical source populations for geographic expansion and genetic diversity or have the potential to develop into prime habitat under a more favorable climate. In addition, currently low value, degraded sites with good potential for restoration have added value if they offer an opportunity to reestablish key habitats and landscape integrity, improving species and system adaptive capacity (e.g., Johnson et al. 2005; Renton et al. 2012). This is not a strategy to select poor sites per se, but to seek value in less favorable locations.

4.15.4.3.3 Tenet 3: Multiple Planning Horizons

Biodiversity conservation planning is by definition for the long-term. However, under a changing but uncertain climate, devising a plan relevant to both current and (indeterminable) future states is problematic. A solution is to develop a multiple-goal conservation plan, where different conservation strategies are developed for different planning horizons ("Establish multiple investment strategies to meet financial goals for different time horizons"). One such multigoal approach is to separately focus on short- versus long-term climate risk, following a scenario of climate change shifting from being moderately to severely disruptive to species and ecosystems over the coming decades – a scenario consistent with fundamental lessons regarding plausible climatic change and ecological vulnerability (see Section 4.15.2, Section 4.15.4.1). These two planning horizons have their parallels elsewhere in species conservation assessment, such as in 10- and 100-year timeframes used for evaluating population reduction and extinction risk in the International Union for Conservation of Nature Red List (International Union for Conservation of Nature 2010).

Moderate Climatic Disruption Strategy

Under a multiple-time horizon approach, conservation strategies for the near-term could consider potential climatic change over, for example, the next 10–20 years to be sufficient to alter population survivorship and landscape processes – but under which species and ecosystems are still capable of local adaptation. Goals would then be to:

- Protect current and restore potentially high-value conservation sites (per Tenet 2)
- Implement measures to protect and enhance species and system adaptive capacity (with respect to climate, other stressors, and their synergisms) and species potential for microevolutionary change.

Corresponding strategies could include the following:

- Supplementing the list of species and systems of conservation concern with those elements not currently considered at risk but which may become so due to their climate vulnerability (e.g., Horn 2011).
- Preferentially increasing conservation goals (quantity and quality of sites) for species and systems identified as most vulnerable to climate change (e.g., Horn 2011; Howard and Carver 2011).
- Selecting landscape units that increase landscape and regional connectivity and increase buffering from other threats to reduce species and system vulnerability (e.g., Kittel et al. 2011c).

These goals and strategies are consistent with conservation practice employed for other threats (Groves 2003), and so do not rely on any innovation other than to treat climate as an additional threat with its own attributes (Kittel et al. 2011c). Ideally, this is a 'no regrets' strategy as it encompasses conservation actions that would have been called for without explicit consideration of climate issues and, by supporting adaptive capacity, has benefits in regard to other threats regardless of whether climate substantially changes or not (Howard et al. 2010; Wilby and Vaughan 2011). These actions are more likely 'least regrets,' as opposed to 'no regrets,' because of implementation or opportunity costs associated with increases in or some shifting of conservation priorities (Wilby and Vaughan 2011).

Severe-Disruption Strategy

In the longer term, such as over the next 70–100 years, we can consider the possibility that climatic conditions could change so much that there is little expectation that ecosystems would be the same or that any species of concern would be locally retained (Araújo et al. 2004; Bachelet et al. 2001). Such a severe disruption requires that we consider substantially different adaptation strategies and conservation goals (Seastedt et al. 2008).

Given the uncertain status of local and regional biodiversity under this scenario, an approach is to look beyond biological attributes of a landscape and consider how the physical landscape supports biodiversity (without any expectation of what ecosystems may arise there with time) (Kittel et al. 2011a). A strategy is to select landscapes (1) for current physical integrity (with little disruption of, for example, hydrologic network function and soil and geomorphologic processes) and (2) to capture a region's physiographic diversity (e.g., based on elevation, slope, aspect, stream order, lake basin attributes, and bedrock geology). Such landscapes may offer the best prospect for retention of intact ecological and evolutionary processes and for future development of new functioning ecosystems (Anderson and Ferree 2010; Beier and Brost 2010; Cowling et al. 1999; Kittel et al. 2011a). As 'enduring landscapes,' these physical landscapes are largely defined by their topographic and geologic character and so are generally not sensitive to climate changes at ecological timescales (unless significant changes in geomorphology result from climate shifts, for example).

4.15.4.3.4 Tenet 4: Expect Surprises—Scenario Planning

As noted earlier, species or system vulnerability is relative to the magnitude and nature of a threat. While moderate- and severe-disruption contexts (Tenet 3) give us the opportunity to develop generalized magnitude-linked strategies, we can also employ 'scenario planning' to consider vulnerability under a suite of more specific, qualitatively distinct alternative future states. Derived from military and business applications for dealing with high uncertainty, conservation scenario planning generates a limited set of 'what if' scenarios selected to reflect the breadth of probable – as well as less probable but still plausible – futures (Peterson et al. 2003). These form alternative reference frames for assessing species and system vulnerabilities on which to base a suite of conservation strategies. This approach can be implemented by a team of experts offering diverse perspectives, drawn from multiple disciplines and professional backgrounds (e.g., from nongovernmental organizations, agencies, and research institutions) (Kittel et al. 2011c; MacMillan and Marshall 2006; Peterson et al. 2003; Runge et al. 2011).

In contrast to projections that (1) suggest a probabilistic relationship between altered drivers and outcomes (with the probability usually implied but not known or quantifiable) (MacCracken 2001) and (2) commonly are used in climate impact assessments (e.g., Fischlin et al. 2007), scenarios reflect the possible rather than just the probable and can be the foundation of vulnerability assessments (Kittel et al. 2011c; Peterson et al. 2003). Scenarios can be general or specific statements of contrasting future states and can be developed from observed system behavior, system sensitivity from model projections, and 'imaginative speculation' – the last is to challenge our thinking about future dynamics beyond those experienced or expected (Peterson et al. 2003; Turner et al. 2003; an example application in conservation planning is given in Horn 2011, Howard and Carver 2011, and Kittel et al. 2011c).

4.15.4.3.5 Tenet 5: Save Aggressively and Early

If uncertainty is so large that site diversity, multiple time horizon, and scenario planning strategies (Tenets 2–4) seem insufficient, the fallback hedge against uncertainty is to implement conservation action more extensively across the landscape ("Save aggressively to counter downside risk"). An example would be to have greater redundancy in the number of sites fulfilling any one goal. This would likely expand conservation site selection into lower priority, low quality areas (e.g., Kittel et al. 2011c) and might call for restoration to realize the potential adaptive capacity of these landscapes. As with any conservation plan, a complementary strategy is to implement its components as soon as feasible given that opportunity costs (lost opportunities) for protecting habitats and landscapes increase with time, as key environments are degraded by other stressors ("Start investing early"); this need is only intensified with climatic uncertainty (Hannah et al. 2007).

In conservation planning, the question of "How much is enough?" is one difficult to address (1) because of uncertainty in future levels of risk from both known and unanticipated threats and (2) because, for more pragmatic considerations, conservation plans often call for a level of action greater than feasible given limited opportunity and financial resources. That said, high uncertainty in climate risk ups the level of critical conservation action needed to reduce the vulnerability of species and ecosystems and should provide additional incentive for action by agencies, conservation organizations, and other public and private stakeholders.

4.15.4.3.6 Tenet 6: Revisit Goals and Strategies—Adaptive Management

A conservation plan for reducing climate vulnerability needs to include a review process for keeping the plan on goal by incorporating monitoring feedback and new information ("Periodically reevaluate financial goals, adjust investment strategies accordingly"). This is to help cope with uncertainties in how conservation strategies will play out due to unexpected species and system dynamics and unanticipated changes in external forcings (including from new threats).

One approach for on going reassessment in conservation planning is 'adaptive management' (Keith et al. 2011). Adaptive management is an iterative process of (1) reassessing species and system status through monitoring, (2) evaluating current and alternative innovative strategies through research and expert elicitation, and (3) adapting conservation plans in light of these new insights (Conroy et al. 2011; Runge et al. 2011; Williams et al. 2007). The adaptive process could include periodic reappraisal of goals, vulnerability assessments, and strategies to take into consideration:

- Observed changes to populations, communities, and ecosystems – including those tied to conservation plan achievements and failures to date.
- Increased understanding of external forcing and internal dynamics.
- New opportunities – such as from new ideas, tools, stakeholders, and government policies.

4.15.4.4 A Vulnerability Approach for Conservation Planning

Consideration of climate in conservation planning often takes the form of impact assessments, where the goal reflects a perceived need to determine specifics of how, where, and which elements of biodiversity might be strongly altered under rapid climate change. Explicitly driven by climate projections, this approach is referred to as 'top down' as it follows the progression of cause and effect. However, this requires skillful prediction and a certainty in future forcings – which, in all practicality, are not achievable (see Section 2.01.2 and Section 4.15.4.2). Consequently, high uncertainty and low predictability limit the value of model projections for conservation planning. Such limitations include that (1) spatial and temporal details in projections are not definitive enough to be relied on for planning, even when downscaled, (2) the use of ensembles of projections to capture a range of outcomes still constrains our outlook, as they (most likely) underrepresent a larger domain of possible futures that may arise from unforeseen or poorly modeled forcings and dynamics, and (3) projections do not necessarily capture critical attributes of climate relevant to understanding ecological, hydrological, and other terrestrial and aquatic processes (such as key variables at appropriate timescales) (Kittel et al. 2011c).

Alternatively, if we acknowledge that high uncertainty in future outlooks cannot be sufficiently reduced, it may be more productive to rephrase our goal to one of decreasing the vulnerability of species and systems (Dawson et al. 2011; Kittel et al. 2011c). This 'vulnerability approach' focuses on enhancing adaptive capacity as a means to lower or cope with risks from uncertainties (Pielke et al. 2012; Turner et al. 2003). In contrast to projection-driven assessments, this is a 'bottom-up' approach as it looks to understand species and ecosystem dynamics that determine their vulnerability (Pielke et al. 2012). This approach focuses on producing planning outcomes that better recognize and handle uncertainties, employing strategies that do not rely on the temporal and geographic details of model projections (Kittel et al. 2011c).

In the vulnerability approach, the investment-analog tenets (see Section 4.15.4.3) give us a framework for handling uncertainty in a 'smart' (appropriate) manner while devising strategies to support the adaptive capacity of species and systems. Stemming from these tenets, planning decisions are facilitated by the integration of expert knowledge, scenario planning, a no-regrets goal, and adaptive management as follows:

- Expert synthesis of established knowledge provides an opportunity to gain insights into the resistance and resilience of species and systems to a changing climate and, based on this, to devise strategies to reduce or cope with this risk (Dawson et al. 2011) (see also Comer et al. 2012; Game et al. 2011; Hannah et al. 2002b; Hansen et al. 2010; Mawdsley et al. 2009).
- Scenario planning gives us the means to not rely on climate and ecological model projections for systems whose complexities are, as previously described, inherently difficult to simulate; rather, scenario planning gives us a framework with which to envision consequences to biodiversity across a broad spectrum of plausible futures (including conceivable 'surprises').
- A no-regrets goal guides us to implement climate-adaptive strategies that benefit current conservation needs by also decreasing species and system vulnerabilities to the suite of other threats.
- Adaptive management protocols give conservation programs the flexibility to adjust strategies to changing conditions and advances in our understanding.

The broader the perspective and more integrative the expert synthesis is in its consideration of fundamental determinants of biodiversity's vulnerability to climate the better. This calls for a suite of short- and long-term (multiple planning horizon) climate-adaptive measures to sustain or restore (1) population viability, dispersal, and microevolutionary processes, (2) trophic, competitive, and mutualistic community networks, (3) landscape disturbance regimes, and (4) ecosystem energy and material flows. The resulting design is to support, at least for the near-term, existing patterns of compositional, structural, and functional biodiversity and, in the longer term, to allow for their potential reconfiguration on the landscape as climatic conditions shift.

Such strategies can be devised and deployed using current best conservation practices, including those for maintenance and reestablishment of the physical and biological integrity of the environment, along with reduction of direct and synergistic effects of other threats. Also derived from the tenets for coping with climatic uncertainty, strategic options include diversification, restoration, enhancement of buffering and connectivity, 'enduring landscape' conservation, and 'save more/save early' actions.

This process is clearly inexact, limited by our understanding of species and system adaptive capacity (see Section 4.15.3) and inherent constraints on environmental predictability. Given the essential yet difficult task of conservation planning in light of biodiversity's vulnerability to climate change, the vulnerability approach, integrated with strategies to handle uncertainty, offers a path for us to prepare, even if reluctantly, for an uncertain ecological future.

Acknowledgments

This work greatly benefited from discussions with colleagues at the Nature Conservancy of Canada (Victoria, BC), Instituto de Pesquisas Ecológicas (Institute of Ecological Research, Nazaré Paulista, Brazil), and The Nature Conservancy. I wish to thank Pierre Iachetti, Hannah Horn, Sara Howard, Gwen Kittel, Matthew Fairbarns, Carmen Cadrin, Alexandre Amaral Nascimento, Fernando Lima, Mariana Vale, Barry Baker, Betsy Neely, John Sanderson, Dennis Ojima, and Jill Baron for their insights re global change biology and biodiversity conservation in the context of climate change. Thanks also to Tim Seastedt and Roger Pielke, Sr., for their valuable comments on the chapter.

4.16.1 Introduction

Globally, biodiversity is being gradually threatened by increased human impact on ecosystems that cause widespread change in the global distribution of organisms by species extinctions and homogenization through species invasion (Vitousek et al. 1997; McCann 2000; Sala et al. 2000; MEA 2005). These impacts on ecosystems and biodiversity alter ecosystem processes, function, and structure and by that change their stability in face of environmental factors. At the moment, we are in the middle of one of the largest experiments in the history of the earth, as the human effects on climate, biogeochemical cycles, atmospheric nitrogen deposition, and the transportation of organisms have altered the local and global diversity with major consequences for ecosystems and society (Chapin et al. 2000). This has profound implications for the provision of services that humans derive from ecosystems.

Directional changes in climate are among the major factors affecting organisms and biodiversity (Hughes 2000; Root et al. 2005; Walther et al. 2005; Parmesan 2006). Therefore, assessing the biodiversity consequences of changes in weather conditions that organisms experience is a multifaceted problem, requiring consideration of all aspects of vulnerability: exposure, sensitivity, and adaptive capacity (Williams et al. 2008), where (1) exposure is the extent of environmental change likely to be experienced by a species; (2) sensitivity is the degree to which the survival, persistence, fitness, performance, or regeneration of a species or population is dependent on the prevailing climate; and (3) adaptive capacity refers to the capacity of a species to cope with change by persisting in situ, by shifting to more suitable local microhabitats, or by migrating to more suitable regions. All in all, vulnerability has been defined as "the extent to which a species or population is threatened with decline, reduced fitness, genetic loss, or extinction owing to climate change" (Dawson et al. 2011). Vulnerability is also due to other environmental change factors and the interaction effects generated by these factors as well as to climate even if it does not change.

In the following chapter, we will discuss and present state-of-the-art knowledge on the climate effects on biodiversity, and biodiversity effects on marine food-web structure. Then more specifically, we will apply the concept of regime shifts to illustrate how vulnerable marine ecosystems are due to alterations in diversity and stability leading to increased risk of regime shifts in changing environments.

4.16.2 Biodiversity and Temperature

Temperature directly affects the physiology of species (Hughes 2000) and species have been shown to shift their ranges in latitude or altitude (Parmesan 2006; Beaugrand et al. 2009) to adapt to changes in temperature. Further, many species alter their phenology to an earlier timing of spring events or a later timing of autumn events (Blenckner and Hillebrand 2002; Walther et al. 2002; Parmesan 2006). Such changes in phenology may affect species interactions and can cause temporal mismatches of predator–prey interactions, resulting partly in ecosystem-wide effects (Stenseth and Mysterud 2002; Beaugrand et al. 2003; Edwards and Richardson 2004).

In addition to physiological and phenological changes, how temperature could affect biodiversity is very difficult to predict, because often it involves a stochastic interplay of multiple drivers (not only climate) acting on diverse spatial and temporal scales. The Intergovernmental Panel on Climate Change predicted that 20–30% of all organisms have a high risk of extinction if the global mean air temperature exceeds 2 °C (IPCC 2007). The cause for such relative high extinction likelihood is related to ecological and/or geographical boundaries wherein species are assumed not able to disperse or to adapt to the new climate conditions. However, changing climate conditions can also open a window of opportunity for new species invasions; if invasion or colonization processes are faster than extinction, biodiversity could increase in given locales. For example, in the North Sea, an increase in the water temperature during the last decades caused an increase in species richness owing to an increase in warm-water species (Beaugrand 2002; Hiddink and ter Hofstede 2008). This illustrates the difficulty to predict a general biodiversity response to changes in water temperature.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00423-8

It is important to note that for most temperature change scenarios, species will not be pushed outside their physiological limits because of changes in temperature. We would expect that more often temperature changes would affect the nature of species interactions. In particular, temperature can affect competitive dominance (Tilman et al. 1986) and further accelerate competitive exclusion (Vijverberg and Vos 2006). Even before species are lost from a system due to such competitive exclusion, changes in the dominance of certain species may have important implications for ecosystem function (Hillebrand et al. 2008). The changes in competition also affect consumption, which alone is strongly temperature dependent. For example, the selectivity and grazing pressure of zooplankton can affect the diversity, evenness, and productivity of phytoplankton (Hillebrand et al. 2007). However, we know little about how diversity is affected by interactions between competitive exclusion, consumption, and temperature, particularly in real life food-webs.

Most of the studies testing climate effects on diversity in marine systems focus on changes in average sea temperature. However, past observational evidences and climate projections argue for a possible increase of variability in these factors. Other human-induced environmental changes increase the risk of extreme values in environmental characteristics which will influence species richness and stability (Carpenter and Brock 2006; Ives and Carpenter 2007). For example, increased variability in salinity (Flöder and Burns 2004), temperature (Descamps-Julien and Gonzalez 2005), and nutrients (Sommer 1985) increase species richness by preventing competitive exclusions. However, the combined effects of the change in the mean and in the variation are very poorly understood and most probably highly ecosystem specific. For example, zooplankton diversity has been found to increase with changes in temperature but to decrease with variations in chemical variables (Shurin et al. 2010).

4.16.3 Diversity versus Stability – a Long Debate

The relationship between diversity and ecosystem stability has fascinated ecologists over decades. In the 1950s, ecologists suggested that a more diverse community enhances ecosystem stability (Odum 1953; MacArthur 1955; Elton 1958). This ecological theory was for a long time mainly based on equilibrium population dynamics. However, populations often show large temporal and spatial variation. Because such variations can significantly influence ecological dynamics, ecologists moved away from an equilibrium-based concept of stability to one generated by temporal variability in environmental factors (McCann 2000). This is of special importance because fluctuations of populations are driven by biotic or abiotic processes, which provide the possibility that a large number of organisms, for example phytoplankton species, can coexist in the water column on a minimal number of resources (see, e.g., the paradox of phytoplankton; Huisman and Weissing 1999 and literature therein).

In general, stability can be measured in several ways (see for different definitions Ives and Carpenter 2007). For example, for a rare perturbation, stability can be measured as the rate as the system returns back to the equilibrium state (May 1973), also defined as engineering resilience (Holling 1996). In cases in which perturbations are stochastic and of higher frequency, stability depends on community resistance (Pimm 1984), which can be measured by the variability in the change of combined species densities over time with repeated perturbations (Ives and Carpenter 2007). These two measures of stability combine to give a third measure: overall system variability. Further, Ives and Carpenter (2007) point to cases wherein stability could be measured as the number of species within an area that are extirpated, or by the compensatory change in combined densities of all species. Another possibility is that perturbations might even cause the invasion of new species and here stability could be measured as the chance that an invader is successful, or the number of secondary extinctions the invasion causes (Ives and Carpenter 2007 and lit therein). These different ways to measure stability illustrates how differently external perturbations can shape the food-web dynamics and thereby the stability.

A majority of diversity-stability studies focus on single trophic level response in the context of relationships. For example, long-term grassland experiments suggested that diversity within an ecosystem tends to be correlated positively with plant community stability measured as the coefficient of variation of plant biomass (Tilman et al. 1996). Functional diversity, rather than species diversity, tends to most strongly relate to stability (Huston 1997; Tilman et al. 1997; Hooper et al. 2005). This is important because the diversity of responses to environmental change among species contributing to the same ecosystem function, which is called response diversity, is critical to stability, that is, ecosystem resilience (Elmqvist et al. 2003). Thus diversity is not the direct driver of the stability of ecosystems (McCann 2000). Instead, it seems that species diversity provides a pool of important ecological mechanisms and response patterns that are essential for the stability in ecosystems. The greater the variances in species responses, the lower the species richness required to insure the ecosystem, also known as an insurance hypothesis (Yachi and Loreau 1999). By further applying the food-web approach instead of the often-used linear food-chain approach, models and experiments showed that natural food-web structures can increase the ecosystem stability (McCann 2000 and lit therein). This valuable insight has led to a discovery of an important mechanism where weakly interacting species stabilize community dynamics by dampening strong, potentially destabilizing consumer–resource interactions. Here the number, distribution, and variability of weak interactions in a food-web can be of high importance (McCann 2000) and any addition or removal of key species can have profound effects on the ecosystem stability (McCann 2000). Thus, decreasing biodiversity may often be accompanied by increases in average interaction strengths among species and a concomitant decrease in ecosystem stability.

4.16.4 The Vulnerability of Ecosystem Stability and Regime Shifts

As described above, in natural systems populations tend to fluctuate around some trend or average. However, populations occasionally experience a regime shift that is characterized by an abrupt change in the structure and function of a system.

Recently, it has been shown in experiments and field data that a gradual change in external drivers (e.g., temperature) can cause an abrupt, nonlinear change in an ecosystem (May 1973; Scheffer et al. 2001; Scheffer and Carpenter 2003; Folke et al. 2004). Even a small change in environmental conditions can trigger a large shift in ecosystems. The reason for such an abrupt shift is the decrease in the ecosystem stability, wherein several factors have eroded the stability (resilience) so that sometimes only a tiny change can act as the straw that broke the camel's back, causing an entire regime shift.

After a system has crossed a threshold, the ecosystem dynamics and functions are different from prior observations (Scheffer et al. 2001). For example, if a lake ecosystem has experienced eutrophication due to the addition of a nutrient load, the ecosystem becomes more dominated by phytoplankton instead of aquatic macrophytes and benthic organisms that are found in less-eutrophied systems. Even if the external input of nutrients is reduced due to improved management options, the turbid, phytoplankton-dominated state is maintained through constant recycling of nutrients from the lake sediment. In order to return to the previous state, nutrient inputs usually have to be reduced significantly below the threshold level that caused the system to transform to the eutrophic phytoplankton dominant state. This phenomenon is known as hysteresis and characterizes many regime shifts.

Hysteresis is a stabilizing mechanism generated by internal feedbacks associated with the existence of different ecosystem stable states or regimes. In general, both negative (i.e., 'damping' or 'stabilizing') and positive (i.e., 'amplifying' or 'reinforcing') feedbacks are an integral part of all natural systems. Negative feedbacks tend to reduce fluctuations in process rates, keeping the system within a particular state. In contrast, positive feedbacks increase changes in processes that destabilize the system. The strength of species interactions determines the strength of the feedbacks and thus the strength of the hysteresis effects.

External drivers, for instance, changes in climate patterns, can overwhelm negative feedbacks and increase the importance of positive feedbacks. If these positive feedbacks are strong enough in relation to other ecosystem processes, they can drive the system across a threshold. Duarte et al. (2009) discussed that in some cases it might not be possible to return the ecosystem to its previous state even if the pressures are reduced far beyond the preshift levels. How much the external forcing needs to be reduced in order to change the system between different alternative states is determined by the internal feedback mechanisms that make these states persistent (e.g., hypoxia in the Black Sea (Oguz and Gilbert 2007)). According to Scheffer et al. (2001), biological feedbacks, especially predation and competition, are important factors in determining the system states and change between them. Nevertheless, to really pinpoint these mechanisms has proved difficult because they vary in space, time, are system specific (Scheffer et al. 2001), and may first be detectable only after a threshold is exceeded. Furthermore, model studies have suggested that changes in internal ecosystem dynamics (e.g., behavioral change such as schooling (Bakun and Cury 1999; Cury and Shannon 2004) can also result in changes in state and not only stabilize a new state (Scheffer et al. 2001; Scheffer and Carpenter 2003).

One should not expect all ecosystems to respond to climate in an abrupt continuous manner. Scheffer et al. (2001) and Collie et al. (2004) describe different response types in ecosystem change based on the relationship between the response (ecosystem) and control (external) variables. This relationship can be linear/smooth, nonlinear/abrupt, or discontinuous, leading to alternate regimes and hysteresis. When studying such responses, it is worth keeping in mind that the ecosystem response reflects the lifecycle length of response 'groups' and hence, for example, plankton organisms are likely to respond faster than those at higher trophic levels (Overton 1972; Wagner and Adrian 2009).

The regime shift concept has increasingly been employed in various ways in describing an array of changes in environments during the past decade. Nevertheless, the problem of defining a change as a regime shift was brought into discussion rather recently. Lees et al. (2006) are one of the first to attempt to set up common criteria for defining a marine ecosystem regime shift. They based their study on previously published descriptions and concluded that the criteria used to define both climatic and ecosystem regime shifts have been very system specific.

According to qualitative criteria, an ecosystem regime shift is a sudden, high-amplitude and infrequent event that has large spatial scale and is detectable in atmospheric and oceanic components as well as affects several trophic levels (Lees et al. 2006). Lees et al. (2006) also demonstrate that many previous studies attempted to quantify regime shifts; meanwhile changes in food-web structure, interaction strength, and dynamics have seldom been recorded. Collie et al. (2004) have also stated that statistical time series analysis is not sufficient on its own to describe regime shifts, but more qualitative mechanistic understanding is needed. In practice, changes in ecosystem indicators, such as species richness and mean trophic level, have been measured, for example, by Tian et al. (2008) in their study of the Japan/East Sea.

4.16.5 Regime Shifts and the Vulnerability of Marine Ecosystems to Climate

Large-scale changes in marine ecosystems with significant environmental as well as economical consequences are observed in increasing numbers worldwide (Cury and Shannon 2004; Folke et al. 2004; Tian et al. 2006; Möllmann et al. 2009). In open sea ecosystems, changes are often associated with overfishing or changes in weather and ocean patterns (Lees et al. 2006). In the case of overfishing, many examples of collapsing, or at least drastically decreasing, fish stocks exist in both coastal and offshore ecosystems (Jackson et al. 2001; Hutchings and Reynolds 2004). Recent declines of cod stocks (*Gadus morhua*) in the Atlantic (Frank et al. 2005), North Sea (Beaugrand 2004), Newfoundland (Hutchings 1996), and Baltic Sea (Casini et al. 2009b) as well as collapses of pelagic fish stocks in the Northern Benguela (Cury and Shannon 2004) and Black Sea (Oguz and Gilbert 2007) are a few well-recognized examples. The best-known stock recovery failure was observed in Newfoundland where cod did not return even after a fishing ban was put into place. Some of the above-mentioned fish stock collapses have also been associated with changes in weather and ocean patterns. The collapse in the Peruvian sardine stock at the beginning of the 1970s was related to El Niño phenomena (Barber and Chavez 1983), and is a prime example of a climate-induced ecological change (Alheit and Bakun 2010). In addition, eutrophication-related ecosystem changes such as the appearance of persistent hypoxia are commonly observed in today's shelf and enclosed seas.

In the following section, we present several cases of marine regime shifts (see **Table 1**) in relation to their timing, the drivers causing the regime shift, the internal food-web dynamics, and characteristics that make the system more vulnerable to change. We limit our scope to published open sea ecosystem changes that are determined as regime shifts by the corresponding authors.

4.16.5.1 Timing of Regime Shifts

The marine ecosystems that are suggested to have undergone a regime shift represent different types of marine environments. The geographical distribution of these ecosystems is wide, but rather Northern Hemisphere centric (**Figure 1**). This is partially explained by the exclusion of coral reef studies from the scope of this study (e.g., Hughes et al. 2007; Norström et al. 2009). Most of the published studies start their time-series from the mid-1960s and continue into the beginning of the present century (**Figure 2**). Two main regime shift periods can be identified, the first at the end of the 1970s and a second, larger one in the late 1980s. The first cluster of studies is mainly composed of regime shifts detected in oceanic Northern latitude ecosystems (Link et al. 2009). During the latter period (1988–90), several independent studies observed regime shifts in ten marine ecosystems with varying characteristics and wide geographical distributions. The timing of the regime shift cluster in the latter half of the 1980s (**Figure 1**) coincides with large-scale changes in the atmosphere, indicated by atmospheric-ocean climate indices such as the Pacific Decadal Oscillation (PDO; Hare and Mantua 2000) and Northern Atlantic Oscillation (NAO, Hurrell 1996). Both indices are calculated by differences in sea-level pressure and consequently sudden changes in seawater temperatures and advection patterns (Hurrell and Deser 2010), often with a connection over large distances (Alheit and Bakun 2010). At present, it is commonly suggested that these changes in the physical environment are closely linked with the marine ecosystem regime shifts observed during that period.

4.16.5.2 External Drivers Causing Regime Shifts

The drivers causing regime shifts can either be single or, most probably, multiple. In many of the marine regime shifts, multiple drivers are found to have initiated the change (see **Figure 3**). Often, the main drivers are atmospheric-ocean patterns, high fishing pressure, and eutrophication initiated by excess anthropogenic nutrient input. However, large oceanic offshore ecosystems form an exception and have been suggested to have undergone regime shifts initiated solely by abrupt changes in atmospheric-ocean patterns (**Figure 3**).

It is worth noting that many studies, especially atmospheric-ocean oriented regime shift studies, wrongly do not consider other drivers in their analysis. Regime shifts suggested to be caused by multiple drivers occurred mostly in coastal areas or semi-enclosed systems. Here the main drivers are climate, fishing, and nutrient loading from land (**Figure 3**). In the Mediterranean Sea, the increase in zooplankton biomass was correlated to changes in climatic conditions, but also an inverse relationship to anchovy biomass was found (Conversi et al. 2010). Hence, it may be misleading to neglect this change in predation pressure when studying the change in zooplankton abundance. Also, in Chesapeake Bay intensive fishing was found to be behind a decline in the total fish stock accompanied by an increase in the pelagic/benthic fish ratio observed after the beginning of the 1990s (Kemp et al. 2005). Hence, even if the

fishery-related regime shift has not been described in Chesapeake Bay, the fishery may have contributed to the regime shift because overfishing could have caused a lower resilience toward the ecosystem change observed in the early 1990s.

4.16.5.3 Food-Web Structure and System Properties

The ecosystems which have undergone discontinuous ecosystem change have many commonalities in their internal dynamics. For example, the presence of hypoxia and eutrophication is a common feature of the current state of the Black Sea, Baltic Sea, Northern Benguela, Gulf of Mexico, and Chesapeake Bay. In most of the regime shift cases with hypoxia, the vicious cycle of nutrients, eutrophication and hypoxia, is the main focus of regime-shift analysis. In the Baltic Sea, Black Sea, and Northern Benguela ecosystems, however, hypoxia is additionally seen as a mechanism that worsens recruitment conditions of important piscivorous and planktivorous fish,

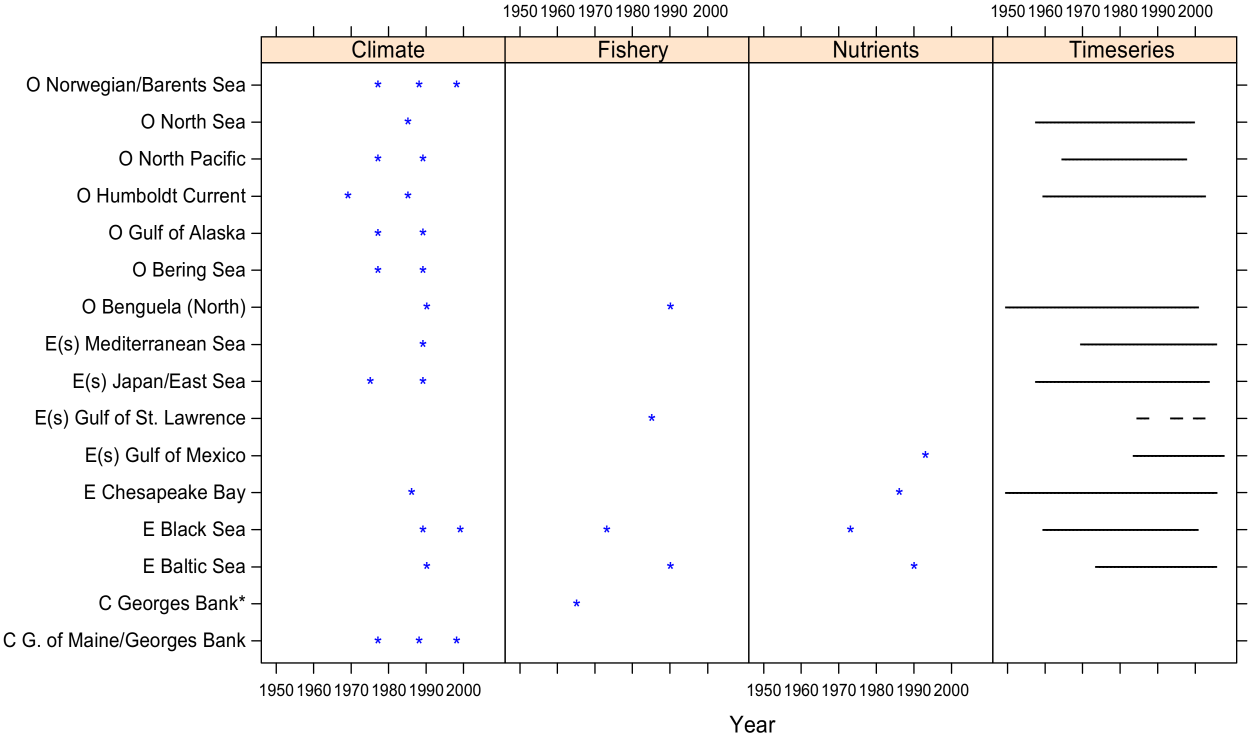

Figure 3 Drivers observed to have caused regime shifts in different types of marine ecosystems (O = oceanic, E(s) = semi-enclosed, E = enclosed, C = coastal) and the length of time-series used in analysis. *Study only on haddock, time-series length 1931–2000 (not included in the graph due to scaling). Information on the length of time-series studied was not available from all studies.

hence altering the top-down control in these systems once present.

Related to eutrophication, invasive zooplanktivore jellyfish have been found to play an important role in stabilizing the new eutrophic ecosystem states in the Black Sea and the Northern Benguela. Jellyfish can efficiently prey on zooplankton and thereby decrease the grazing on phytoplankton in these ecosystems (Cury and Shannon 2004; Oguz 2007; Oguz and Gilbert 2007; Oguz et al. 2008). They also efficiently compete for zooplankton prey with planktivorous fish, but themselves are nutritionally poor, and the energy they contain is not channeled to upper trophic levels. The jellyfish (*Mnemiopsis* sp.) have been suggested to appear in the Southern Baltic Sea during the past years (Lehtiniemi et al. 2007; Gorokhova et al. 2009).

Several feedback mechanisms have been suggested (Fauchald 2010) that can contribute toward hysteresis in relation to ecosystem change. These are predator–prey reversal (Köster and Möllmann 2000; Walters and Kitchell 2001), recruitment competition or piscivore preying on planktivorous species that compete/prey on juvenile piscivores (Walters and Kitchell 2001), size-selective predation, and food-dependent growth (see for a model study De Roos and Persson 2002), as well as change in behavior due to risk effects (Willis 2007). Fauchald (2010) emphasizes that these internal feedback mechanisms involve trophic top-down interactions and have also been described to take place between piscivorous predatory fish and their planktivorous prey. In the Baltic Sea, the delayed recovery of cod after decrease in fishing pressure may have to do with cod egg predation by pelagic planktivore sprat (*Sprattus sprattus*), which has exploded after its release from the predation control of cod (Köster and Möllmann 2000). In the North Sea, increased herring stock (*Clupea harengus*) is thought to predate on cod eggs (Fauchald 2010). In the Baltic Sea also, resource competition between cod larvae and adult cod prey sprat has been documented. Both, cod larvae, and sprat prey on the zooplankton *Pseudocalanus* sp. (Möllmann et al. 2004) and the recent cod abundance is too low to control the sprat population (Casini et al. 2009b). Model studies have also indicated that once cod is abundant in the Baltic Sea, the cod may be capable of shaping the size spectra of its prey population to benefit its growth and vice versa (Van Leeuwen et al. 2008). In general, there seems to be a general shift from pelagic or benthic piscivore-dominated systems into ones dominated by small pelagic forage fish (Frank et al. 2005). Out of the hysteresis-displaying systems, the Black Sea (Daskalov et al. 2007b; Oguz and Gilbert 2007), Baltic Sea (Möllmann et al. 2008; Casini et al. 2009b), Gulf of St. Lawrence (Savenkoff et al. 2007), Chesapeake Bay (Kemp et al. 2005), and Georges Bank (Collie et al. 2004) have undergone such a change.

Despite multiple drivers seeming to be connected with discontinuous regime shifts in marine systems, increased nutrient loads or implementations of fisheries are suggested to be able to initiate such a shift on their own. Out of these, the fishery can act as a top-down or wasp-waist (mid-trophic level) control (Cury et al. 2000) and nutrient loads in addition can exert bottom-up control, or wasp waist control via worsened fish breeding conditions due to eutrophication. On the contrary, none of the regime shifts initiated by climate alone shows indication of being discontinuous. This brings up a question whether the ecosystem or populations vulnerability to climate results in a discontinuous regime shift in marine environment. For example, changes in temperature and salinity have been shown to affect fish recruitment success (Köster et al. 2005). Changes in local and regional climatic conditions could alter food-web structure and interaction strength also via altering the top-down and bottom-up dynamics or via change in the functional group diversity caused by extinction and/or invasions of species. Further, it has been suggested that before species are locally extirpated, change in the dominance of these species must occur much earlier (Hillebrand et al. 2008). Increases in temperature can shorten generation times and change interspecific interaction dynamics, which might lead to an increase in species turnover without any change in species richness. Hillebrand et al. (2010) found that temperature increases species turnover and thereby decreased the compositional stability of communities and the functional stability of ecosystem processes without changes in species richness. This again indicates that species richness alone is not a good indicator for the stability in ecosystems and its vulnerability to climate as well as other drivers. Further, local species turnover shown by Hillebrand et al. (2010) will be mediated by more regional changes in species turnover induced by changes in regional climate (Parmesan et al. 1999).

In general, system properties that have been suggested to contribute to stability and herewith to the potential regime shift occurrence in various ways comprise unoccupied space for sessile organisms (Dunstan and Johnson 2004), functional richness (Hooper et al. 2005; Hughes et al. 2005), and species richness (see, e.g., Hooper et al. 2005; Balvanera et al. 2006; Ives and Carpenter 2007).

Frank et al. (2007) suggested species richness to be related to the type of trophic control within the system at each site. Results from the study by Frank et al. (2007) suggest that the level of species richness can be linked to the type of trophic control the ecosystem exhibits. The internal trophic control is thought to play an important role in stabilizing alternative ecosystem states (Scheffer et al. 2001), and species richness is seen to contribute to system resilience.

The restricted water and species exchange in more enclosed systems may limit the dispersal of species and hence also limit functional response diversity, which could explain the more frequent regime shifts in enclosed systems. Further, different anthropogenic drivers also can exert stronger pressure on enclosed systems especially when the coastline and catchment areas are highly populated, which often coincides with high nutrient loads and associated hypoxic areas such as the Baltic Sea.

4.16.6 Outlook

Knowledge on the effect of biodiversity on the food-web structure and stability is still incomplete, despite the very comprehensive and ongoing focus in science. This short overview has, however, shown that biodiversity plays an important role in shaping ecosystem structure and function. In addition, biodiversity seems to be an important component in determining the vulnerability of ecosystems to climate.

It was shown here that a change in ocean and atmospheric weather patterns has triggered several regime shifts within a wide geographical area, but even so the mechanisms behind such changes are still unknown. The group of marine ecosystems showing signs of hysteresis possess some common characteristics, such as enclosed bathymetry and the exposure to multiple anthropogenic drivers. The combined strength of anthropogenic forcing can be larger in these systems or the system resilience may be lower than in more open and/or diverse marine environments. Previously, Collie et al. (2004) have stated that discontinuous regime shifts might not be observable in oceanic ecosystems because they are not spatially confined, hence supporting the observation that marine ecosystems with enclosed nature might be more vulnerable to discontinuous change than open offshore areas. In addition, hypoxia seems to be present in many of the ecosystems suggested to have undergone a discontinuous regime shift, potentially implying that benthic–pelagic coupling has a role in hysteresis-related positive feedback mechanisms. Because hysteresis is a time-dependent phenomenon, the species lifecycle and their interaction strengths are most probably important factors when determining the potential occurrence of discontinuous dynamics. In case of long-lived species, one has to take into account the potential time lag in response and also be prepared that clear abrupt shifts might not always be observable in the time-series of longer-lived species despite whether a discontinuous change would have taken place (Spencer and Collie 1997).

The Baltic Sea is a well-known example of an ecosystem suggested to have undergone an ecosystem-wide discontinuous regime shift in the end of the 1980s (Casini et al. 2008; Möllmann et al. 2009; Alheit and Bakun 2010). Sudden changes in the winter climate (North Atlantic Oscillation, NAO) together with high fishing pressure and a long stagnation period are thought to be shift-triggering causes. Low levels of Baltic cod biomass, explosion of sprat abundance as well as great changes in the abundance of zooplankton species such as *Pseudocalanus* sp. (decrease) and *Acartia* spp. (increase) are characteristic to the new suggested ecosystem state. The winter climate returned back to its pre-1990s state around the late-1990s (Möllmann et al. 2009). However, cod, sprat, and zooplankton species have not yet shown significant change toward their preshift abundances (note that very recently cod stock has shown some signs of recovery as a response to lowered fishing pressure). In addition to changes in fishing pressure, the current internal control mechanisms in the Baltic are suggested to differ from those before the change (Casini et al. 2009a,b). Hence, one can question if the previous zooplankton abundances will be detected in the future or will the predation control on *Pseudocalanus* accuses continue to be a more important control mechanism than the environmental driver of salinity (Casini et al. 2009a,b). Also, on a more general level, it is difficult to say if any marine ecosystem can return to the pre-change ecosystem state due to continuous changes in species composition and internal ecosystem dynamics (Duarte et al. 2009). In other words, ecosystems are a moving target. Even if some individual ecosystem targets might be met from a management point of view, one must be aware of that the return to the desired state might not be ecosystem wide and the current ecosystem response can differ from the previous (Duarte et al. 2009).

The type of response, potentially including discontinuous dynamics, together with changes in internal ecosystem dynamics are seldom more than discussed in the context of marine ecosystem regime shifts. Here, a strong link to ecological theory on diversity and stability is necessary to better understand the ecosystem processes.

Furthermore, it is still debated whether the feedbacks of the discontinuous dynamics need to break down in order for a new, possibly more desirable regime to take place. Such a case has been indicated by model studies (see, e.g., Alley et al. 2003; Oguz 2007), but has proven to be difficult to show in actual ecosystem observations. Regarding ecosystem management, it is of high importance to identify discontinuous dynamics from more linear and smooth changes in ecosystems (Collie et al. 2004), because such systems would require a different management strategy, that is, the reduction of the pressure variable below the threshold ranges.

In many cases it is also challenging to evaluate whether the described change really is ecosystem wide or if a more 'species-replacement' type phenomenon has taken place (Cury and Shannon 2004). To tackle this uncertainty, for example, Tian et al. (2006) have used Simpson's diversity index, mean trophic level in catch, and piscivore/zooplanktivore ratio as ecosystem change indicators. To determine ecosystem vulnerability to external drivers, for example climate, one may employ a common set of methods and indicators to clearly define stability, regime shifts, and hysteresis in experiments, models, and real ecosystems. The significance of earlier detection of change would be great, because currently, the loss in ecosystem resilience and the threshold is often detected only after the threshold has been passed. Some modeling and time-series studies have already been able to give indications for signs of loss in resilience (Biggs et al. 2009). For example ecosystem components may show an increase in variability and change in frequency (Carpenter and Brock 2006), changes in skewness (Guttal and Jayaprakash 2008), slowed down system response (increased autocorrelation) to small perturbations (Dakos et al. 2008), and/or change in the spectral density ratio (Biggs et al. 2009). Such methods have yet to be proven as widely applicable to observational data series that often display a low signal to noise ratio from various environmental drivers and may not be long enough or have sufficiently fine time-resolution. Also these methods might be difficult to apply on higher trophic level organism responses beyond the modeling approach because they have longer life cycles and hence the time-series are likely to display high autocorrelation by default. In the context of marine ecosystem regime shifts, Beaugrand et al. (2008) have recently described an increased ecosystem variability based on time-series data in the north Atlantic. In addition to quantifying and qualifying regime shifts it would be beneficial to describe ecosystem properties in cases in which external drivers have changed drastically but the ecosystem stability was high and therefore no regime shift occurred. That would give a better understanding of (1) the vulnerability of species, in particular following the concept described in Williams et al. (2008) and Dawson et al. (2011), (2) the response diversity, and (3) the strength in interactions, which all most probably provide system stability.

Glossary

Bottom-up control When soil water and nutrient supplies and plant productivity control the abundance of consumer species and ecosystem functioning.

Community disassembly A nonrandom process that disrupts species interactions leading to alteration of species co-occurrence patterns and loss of ecological functioning.

Ecosystem services The suite of natural resources and ecological functions that benefit human livelihoods and well-being. Examples include provisioning of clean drinking water and decomposition of organic wastes.

Indirect effect The effect of one species on another that is mediated by a third species. For example, predators may indirectly benefit plants by consuming herbivores that eat plants.

Phenological mismatch A condition in which the timing of life-cycle development of interdependent species becomes asynchronous due to the differential ability of species to adjust to environmental changes. Phenological mismatches mean that species may miss the peak period of their food production when they begin to breed, potentially leading to declines in their populations.

Regime shift A rapid reorganization of ecosystems from one state to another. Regime shifts can lead to changes in co-occurrence patterns of species and alter provisioning rates of ecosystem services.

Top-down control When top predators control the species composition and functioning of an ecosystem.

4.17.1 Introduction

An ecological system – ecosystem – can be envisioned as a conception of nature that considers biotic communities comprised of a diversity of species and the biophysical environment as an integrated whole. Species within ecosystems are functionally linked through an intricate network of feeding interdependencies, called food webs, which convey nutrients and energy throughout the ecosystem. The biophysical conditions (soil properties, geology, climate, etc.), in turn, set the context that determines the nature and strength of species interactions and ensuing ecosystem functioning. This conception essentially describes a natural economy of production and consumption chains within which species assume one of four basic functional roles (Figure 1). Plant species (primary producers) draw up water and nutrients from the soil and carbon dioxide from the air and are stimulated by sunlight to convert those different chemicals into tissue. Herbivore species (primary consumers) in turn eat that plant tissue, manufacture and produce animal tissue, and are themselves eaten by predator species (or secondary consumers) that further produce animal tissue. Individuals of plant, herbivore, and predator species that are not eaten by their respective consumers eventually die from aging and the chemical elements of their body are recycled back into the soil by decomposer species.

4.17.2 Food Webs and Ecosystem Services

Fundamentally, food webs are the building blocks that produce the suite of natural resources (fisheries, timber, wildlife game, grazing lands, and natural foods like berries, grains and mushrooms) on which human livelihoods and economic well-being heavily depend. Humans, as ultimate consumers, rely on an appropriate production from all four functional groups of species within food webs. For example, in fisheries, humans typically select predator species (e.g., tuna, swordfish, salmon, and trout) directly from the top of the food web. Game hunting focuses directly on herbivore species (e.g., moose, deer, elk) in the middle of the food web. Timber harvesting focuses on plant

Climate
Species exploitation and habitat loss
Natural economy
Plants
Herbivores
Carnivores
Decomposers
Nutrients
1. Ecological interactions
Weakening of species interactions
Phenological mismatch
Loss of ecosystem regulatory capacity
Rewiring of food web
Community disassembly/reassembly
2. Ecosystem service change
Altered nutrient cycling
Lower herbivore and carnivore production
3. Mitigation possibilities
Reduce species exploitation
Preserve large tracts of habitat
4. Policy implications
Encourage preservation of species in upper levels of food webs
Move from single species management to whole ecosystem management that conserves species interdependencies

Figure 1 Schematic illustrating how climate change may potentially influence terrestrial food webs and associated ecosystem functioning and services. Species of plants, herbivores, carnivores, and decomposers belong to a natural economy. Through their feeding interdependencies, species cycle nutrients and convert nutrients into production. Humans currently exploit plant and animal production for food and for materials. Climate change is expected to influence herbivore and carnivore species, most leading to disruption of nutrient flows and production within the natural economy, and hence, loss of important services to humans. Policies should be developed to protect the natural economy, as a whole, through measures that reduce over-exploitation of herbivores and carnivores and that maintain intact food webs across large tracts of habitats.

species (hardwood and softwood trees) at the bottom of the food web. Humans also appropriate production from food webs by replacing wild grazing herbivore species (e.g., deer, antelope, kangaroos) with domesticated herbivores such as cattle and sheep. Humans can transform and erode food webs through various means such as overexploitation, land conversion from one use to another (e.g., conversion of tropical forests to soybean croplands), through predator control measures that are intended to protect domestic herbivores on grazing lands, and through habitat fragmentation consequent to urbanization. (see Chapter 2.1). Climate change adds a layer of complexity, because species in different parts of the food web will be differentially affected by altered climate statistics (**Figure 1**). In particular, herbivore and carnivore species in upper parts of the food web stand to be affected more than plants. This chapter shows how the nature and level of ecosystem functioning is most sensitive to the loss of these species and why their functional role in ecosystems can be considered more brittle (less resilient) than that of species (e.g., plants) lower down in the food web (Dobson et al. 2009).

4.17.2.1 Food Web Control Over Ecosystem Functioning and Services

Species in food webs contribute to ecosystem functioning and production of services by controlling how nutrients and energy are conveyed and transformed within ecosystems (Vanni 2002; Wardle and Bardgett 2004; Schmitz et al. 2010). Classic thinking in ecology and management holds that nutrient supplies to the bottom of food webs control ecosystem functioning and service provisioning (Schmitz 2008). According to this view, the effects of enhanced nutrient supply should flow up the food web to enhance plant production. Because herbivore and carnivore production is built on plant production, increasing plant primary productivity should enhance the abundance of all species in a food web. It, thus, logically follows that losing or supplanting natural consumer species in upper parts of food webs should have little, if any, bearing on overall ecosystem functioning. However, this view is outmoded (Duffy 2003, Schmitz et al. 2010; Estes et al. 2011). Consumer species exert important negative feedback from the top down to regulate natural resource production through a variety of mechanisms. Thus, adopting a food web perspective to resource management necessarily calls for a bidirectional view of control that includes negative top-down feedback in addition to bottom-up control.

One of the most straightforward examples of negative feedback is the direct effect of predators on prey populations. Empirical syntheses show that vertebrate and invertebrate predators can directly reduce the population sizes of their prey by 25–45% (Salo et al. 2010). Empirical syntheses have further shown that predators can indirectly enhance the abundance of plants by 20–80% through direct interactions with prey (known as a trophic cascade) (Borer et al. 2006). In contrast, empirical syntheses show that enhanced nutrient supplies to plants through fertilization can double plant biomass, but that such enrichment does not carry upward to affect herbivore abundances (Borer et al. 2006). This shows that there is asymmetry in the degree to which bottom-up and top-down effects penetrate food webs to control species abundances.

If negative feedback from consumers can affect plants, then it stands to reason that it should also affect the abundance of different nutrients that determine plant production. Empirical evidence shows that this is indeed the case and arises from a suite of mechanisms that again call into question the primacy of the classic view of control over ecosystem functioning (Schmitz et al. 2010). The classical view holds that microbial species are the most critical driver of ecosystem nutrient dynamics owing to their capacity to convert organic matter into mineral elements for plant uptake and production. Microbial action is thus, believed to be the rate-limiting step in the delivery of inorganic nutrients for primary and secondary production in nutrient limited systems. But animal species can directly and indirectly control the fate of nutrients in ecosystems, and may sometimes circumvent the need for microbial mineralization altogether, depending on how and where nutrients are consumed, translocated, and eliminated. These effects emerge because animals can excrete inorganic nutrients (e.g., urine and guano), they can change the nutrient quality of uneaten organic plant and animal material that eventually enters the soil to be decomposed (and hence indirectly exert control over the rate of decomposition), and they can determine how nutrients are translocated spatially within and across ecosystem boundaries (Vanni 2002; Wardle and Bardgett 2004; Schmitz et al. 2010).

The effects of top-down feedback from animals can be substantial. For example, grizzly bears and river otters consume a variety of fish species from rivers. These consumers carry nutrients from fish up to 1000 m away from streams and redistribute them to localized upland latrine sites into which inorganic nutrients (such as nitrogen and phosphorus) are released (Gende et al. 2002). On a watershed scale, this nutrient input can amount to 15–17% of the total nitrogen content of tree foliage. The nutrient translocation by bears to just the riparian zone (within 500 m of rivers and streams) can amount to 24% of the total riparian zone nitrogen budget. On an area basis, this level of fertilization approaches inputs use by forest managers to sustain timber production in similar kinds of ecosystems.

In some habitats, prey species tend to be disproportionately vulnerable to predation leading to differences in the overall distribution of live prey and locations where they tend to be killed across the landscape. These kill sites, in turn, may become nutrient ‘hotspots.’ For example, on Isle Royale, United States sites containing wolf-killed moose receive a 100–600% higher input of nitrogen, phosphorus, and potassium to the soil relative to nonkill sites (Bump et al. 2009). This input translates into a 25–47% increase in mean foliar nitrogen that lasts for between 14 and 24 months; and a 25% increase in mean foliar quality (measured as the foliar carbon to nitrogen ratio) that lasts even longer (three growing seasons).

Predators carry prey carcasses away from hunting sites to feeding sites (known as central place foraging). This behavior also redistributes nutrients across landscapes. For example, bears can distribute marine-derived nutrients from fish to the surrounding forest by carrying 42.6–68.1% of the salmon they kill away from streams (Schmitz et al. 2010). Such behavior is also evident in a hunting wading bird, the limpkin, which preys on wetland snails that are evenly distributed across open water within the wetland. Up to 80% of captured snails are carried to and consumed within local patches of emergent vegetation (Schmitz et al. 2010). Nutrients derived from empty snail shells and unconsumed snail tissue can enhance levels of total plant biomass and aboveground nitrogen and phosphorus in plants by five fold relative to control plots without limpkins. Input from snail remains is the dominant source of nutrients to these patches, which cover 16% of the area, and create marked heterogeneity in productivity, and patch structure across the wetland landscape (Schmitz et al. 2010).

As mentioned above, predators are most notable for their functional role in controlling prey abundance. Their presence or absence in an ecosystem can have large effects on ecosystem structure. Such strong effects are especially evident on Alaskan islands that have breeding seabird colonies. Sea birds subsidize island nutrient budgets with massive inputs of marine-derived guano. Invading arctic foxes and rats has caused severe reduction in colony sizes that in turn has caused a 98% reduction in guano input (Croll et al. 2005; Estes et al. 2011). The loss of this natural fertilizer has caused dramatic changes to the composition of the plant community that, in some cases, has completely transformed island ecosystems from tundra grassland to tundra shrubland. Finally, a long-term study revealed that levels of plant diversity and plant productivity in a grassland ecosystem comprised of hunting spider predators, grasshopper herbivores and herbaceous grasses, and forbs are governed largely by food web interactions among the top spider predator that causes a generalist grasshopper herbivore to take evasive action by foregoing feeding on preferred grass and hide in and forage on a competitively dominant goldenrod species (Schmitz 2004). Such predator-induced grasshopper suppression of the dominant goldenrod plant alters plant productivity and enhances plant species diversity. A predator removal experiment revealed the release from top-down control enabled the goldenrod to proliferate and overwhelm the plant community within 2 years, because in the absence of predators, grasshoppers significantly reduced feeding on goldenrod and resumed their heavy impact on grasses (Schmitz 2004). Attempts to restore top-down control by reintroducing spider predators failed, because the goldenrod became so abundant that grasshoppers were incapable of suppressing its abundance when they again switched to this resource in the face of predation (Schmitz 2004). In very short order, loss of the top predator caused the ecosystem to undergo a regime shift in which it abruptly tipped from a top-down controlled state to a bottom-up controlled state that was impossible to recover after predators were reintroduced.

The mere threat of predation in prey can also have important implications for ecosystem nutrient cycling. Fear of predation heightens prey stress that in turn changes prey nutrient demands largely from protein nitrogen to support growth and reproduction to soluble carbohydrate carbon to fuel heightened metabolism induced by stress (Hawlena and Schmitz 2010). As described above, grasshopper herbivores select nutrients from a mixture of meadow grasses that offer high levels of protein nitrogen and herb species, specifically the competitively dominant goldenrod plant that provides both a refuge from predation, due to its leafy structure, and an important nutrient source owing to its higher soluble carbohydrate. Chronic physiological stress alters the nutritional quality of organic material input to the soil via three pathways. Chronic predation risk leads to lower nitrogen content in herbivore body tissue, and thus a 6% higher carbon to nitrogen ratio than control conditions, available for decomposition. It also leads to a concomitant 5% higher feces carbon to nitrogen ratio than in control conditions (Hawlena and Schmitz 2010). Finally, chronic predation risk leads to a reduction in the quality (10% higher carbon to nitrogen content than in control conditions) of herb plant tissue that eventually becomes litter (Hawlena and Schmitz 2010). Poorer quality organic matter, as determined by higher carbon to nitrogen ratios, is more recalcitrant to decomposition and can lead to a three fold reduction in carbon mineralization to CO_2 (and hence greater organic carbon retention in soils) relative to predator free conditions (Hawlena et al. 2012). Thus, predators may indirectly control functioning of decomposer species and consequently change decomposition rates.

A dramatic case of ecosystem-wide effects of top-down animal control over ecosystem functioning is revealed in a long-term study of the linkages among herbivore abundance, grazing, wildfires, and the carbon cycle in the 25 000 km^2 Serengeti-Mara ecosystem in East Africa. Prior to the 1960s, Serengeti wildebeest were decimated by disease from introduced domestic cattle and poaching from a once high abundance of about 1.2 million animals down to about 300 000 (Holdo et al. 2009). As a consequence, 80% of the ecosystem was burned annually by wildfire because ungrazed grasslands built up large fuel loads each year. These wildfires also decimated savanna woodlands. Since the 1960s, wildebeest recovery has reversed the trend in spatial extent of the wildfires, and indeed, every increase of 100 000 animals translates into 10% less area burned (Holdo et al. 2009). The wildebeest population seems to have recovered to its historically high level, which in turn has restored the grazing regime and the savanna woodlands. These changes to ecosystem plant structure have also transformed the Serengeti ecosystem from being a net source of carbon to the atmosphere, to a net sink of carbon from the atmosphere. The carbon is stored in tree biomass and in organic matter within soil pools (Holdo et al. 2009). The annual amount of carbon that is now stored in this ecosystem is sufficient to offset annual carbon emissions from air travel to East Africa (Dobson 2009; Holdo et al. 2009). By contrast, three times this amount of carbon was released into the atmosphere when wildebeest were at their lowest abundance (See Chapter 3.1.2).

4.17.2.2 Vulnerability of Food Webs and Ecosystem Services to Human Impacts

Human impacts tend to be unequally distributed throughout food webs. Growing evidence reveals that consumer species in upper parts of the food web, especially predators, tend to be disproportionately vulnerable to human impacts, because they require absolutely more habitat space than other species, they are often either the focus of harvesting or the target of persecution when human–wildlife conflicts arise, and they succumb from unwitting management mistakes that arise from well intentioned efforts to enhance their abundances (Dobson et al. 2009; Strong and Frank 2010). Loss of a few key species can trigger a cascade of further changes to the species composition and the degree of feeding interdependencies among remaining species in food webs, a process known as community disassembly (Zavaleta et al. 2009). Community disassembly can ultimately compromise ecosystem structure and functioning, sometimes with spillover or indirect effects that reach far beyond the focal food web itself.

As one example, a major portion of grassland ecosystems in the western United States has been appropriated for cattle grazing and cereal crop production that latter being heavily reliant on water for irrigation. Historically, grasslands harbored large predators like wolves and grizzly bears. But these predators preyed on cattle and thus, jeopardized the cattle industry. Because of the threat to human livelihoods, these large predators were systematically extirpated from much of their historical range. This has had the linked consequence of loss of water quality and quantity via effects that propagate through the food web (Beschta and Ripple 2006). Over the long term, loss of predators is linked to an increase in the densities of native herbivores such as elk and moose. These species have at times reached such high abundances that they were able to damage riparian habitat through overbrowsing. The loss of species that are reliant on riparian habitat notwithstanding, overbrowsing can destabilize river and stream banks leading to bank erosion, alteration of river and stream channels with attendant effects on the water table, water quality, and intensity and volume of water flow – the very water that is needed to irrigate cereal crops (Beschta and Ripple 2006). Eliminating an important predator species to mitigate threats in one agricultural economy can thus, unintentionally lead to a serious threat to another agricultural economy. Another example concerns management efforts aimed at enhancing the abundance of landlocked Kokanee salmon in several lakes in Montana (Spencer et al. 1991; Ellis et al. 2011). Managers introduced freshwater shrimp to those lakes in order to supplement the Kokanee's diet and enhance the production of this important fishery. But, the salmon did not eat the shrimp. Moreover, the shrimp were voracious predators of an important natural food source for the salmon causing the collapse of the salmon fishery. This loss had ripple effects to the surrounding food webs in terrestrial ecosystem because many species of birds and mammals, including bald eagles and grizzly bears, depend on spawning salmon, as a key food source (Ellis et al. 2011). Here, food web manipulations to enhance an economy unintentionally lead to its collapse with attendant threats to a linked adjacent food web.

These unintended management outcomes stem largely from a classical management worldview that food web structure and ensuing ecosystem functioning is unidirectionally controlled from the bottom-up. The unintended outcomes also arise because of a management focus on single species or resources, with limited if any considerations of how those species and resources are directly and indirectly linked through the lines of dependency in food webs.

The recognition that there is asymmetry in the degree of top-down and bottom-up control of ecosystem functioning due to food web interactions and feedbacks means that ecosystems are differentially vulnerable to human-caused loss of species from different parts of the food web (Duffy 2003; Strong and Frank 2010). Because the loss of species in upper parts of the food webs has far greater ripple effects than do losses of species lower down in the food web, the nature and level of ecosystem functioning is more sensitive to the loss of these species compared to species lower down in the food web. Hence, the functional role of upper level species (especially predators) is classified as being more brittle (less resilient) than that of species (e.g., plants) lower down in the food web (Dobson et al. 2009). This brittleness has important implications for understanding the effects of climate on ecosystem functioning, because climate also has disproportionate effects on species in upper trophic levels of food webs, and thus, stands to conflate the effects of humans on ecosystems (Voight et al. 2003; Zarnetske et al. 2012).

4.17.3 Climate and Ecosystem Structure and Functioning

Climate can alter ecosystem functioning and services by altering the lines of dependency among species in food webs in several ways (Harrington et al. 1999; Schmitz et al. 2003; Tylianakis et al. 2008; Traill et al. 2010; Van der Putten et al. 2010) (Figure 1). Temperature and precipitation changes, for example, can alter the strength and hence, relative importance of top-down and bottom-up control possibly leading to a shift in ecosystem state – called a regime shift – and alteration of ecosystem service provisioning (Schmitz et al. 2003). Climate can have differential effects on species in food webs by altering the level of the factor controlling their populations (Stenseth et al. 2002; Traill et al. 2010). Temperature and precipitation changes can alter the synchrony in timing of life-cycle development of species of prey and predator – called phenological mismatch – that compromises existing feeding dependencies because prey availability becomes less reliable (Post et al. 2008; Both et al. 2009). As a consequence, the feeding dependencies among species go awry leading to loss in levels of ecosystem services like production (Figure 2). Finally, these alterations in typical weather patterns can disassemble existing food webs by changing the way species interact with each other (e.g., cause a switch from being competitors with each other to being predators of each other) or reassemble food webs in new ways depending on how species forge new feeding dependencies (Barton and Schmitz 2009). The following highlights case examples of these different effects.

4.17.3.1 Weakening of Species Interactions due to Differential Vulnerability of Species to Climate

Species within food webs do not respond in identical ways to climate owing to differences in their susceptibility to variations in weather patterns. This variation may affect how and when top-down and bottom-up factors control their abundances.

El Niño Southern Oscillation (ENSO) is a phenomenon that NAO creates periodic changes in weather patterns. ENSO in particular causes large changes in rainfall events that cycle over a 5-year period. A 14-year field study in an arid Chilean ecosystem revealed that influxes of high rainfall during ENSO events became manifest in different ways in the food web (Lima et al. 2002). The food web was comprised of three dominant mouse species, each have differing diets ranging from entirely herbivorous, omnivorous (herbivorous and insectivorous), and entirely insectivorous. Each mouse species' abundance fluctuated with ENSO periodicity because their resources varied strongly with the amount of water input from rainfall (a bottom-up control). However, the strictly herbivorous mouse species was also strongly controlled by two owl species (a top-down control), because it is the owls' preferred food resource. Consequently, the abundance of this mouse species fluctuated much less with ENSO periodicity than did the other two mouse species. This shows again that top-down control by predators may be an important stabilizing factor on species dynamics in food webs with respect to climate.

Another field study spanning 20 years examined how among year differences in the abundances of herbaceous plant species, insect herbivores and arthropod predators could be

Figure 2 Depiction of a cyclic natural economy in which production by species lower in the food web (e.g., plants) supports production of species like herbivores and carnivores higher up in the food web. (a) All species in a food web take up nutrients and convert them into production. Species return nutrients back to the soil through waste elimination or carcasses. (b) Under normal conditions, the timing of production and nutrient recycling among the levels of the food web are synchronized among the seasons (phenological matching), so that species in upper levels of the food web can take optimal advantage of production of their prey. (c) Climate change can disrupt the synchrony in timing (phenological mismatch) leading to loss of production in the upper part of the food web. The amount of production lost (darkly shaded gray) increases with the degree of phenological mismatching. Humans rely heavily on herbivore species (meat production) and on carnivore species (fisheries) whose production stands to be jeopardized by climate change.

explained by among year variability in weather patterns (Voight et al. 2003). Species sensitivity to these patterns was measured as the amount of among year variation in species abundance that could be explained by among year variation in weather. This is a useful index because high interannual variability in species abundance means that a species' functional role in an ecosystem becomes less reliable than when the species varies less (Voight et al. 2003). The study revealed that plant abundance was comparatively insensitive to climate and that sensitivity increased as one progressed to species higher up in the food web. Weather patterns explained 1.4–1.8 times more variation in herbivore abundances than plant abundances; and 1.6–2.3 times more variation in predator abundances than plant abundances. Variability in species abundances may arise in this case because of phenological mismatch.

4.17.3.2 Phenological Mismatch and Dissolution of Feeding Dependencies

Phenology, or annual timing and progression of species' lifecycles, is synchronized across food webs. For example, temperate forest birds time their spring migration arrivals and their mating as closely as possible to peak hatching times of their insect prey, such as caterpillars in forest canopies, in order to provide ample food for their nestlings (Both et al. 2009). Hatching of caterpillars is timed to coincide with forest tree bud burst and leaf development because fresh, new leaves are nutritionally superior to older leaves. Spring temperature is an important cue that triggers this chain of events. Any changes in such climate metrics could change the timing of these life-cycle events. The change in timing would not be problematic if species could maintain their synchrony. Instead, we are seeing increasing asynchrony that is leading to a mismatch between species and their food – hence phenological mismatch – that is exacerbated as one moves to species higher up in the food web. Long-term study of a European forest ecosystem revealed that caterpillars seem to have adjusted quickly to the progressive 20-day advance in spring bud burst over the last 20 years. Songbirds that rely on these caterpillars have also adjusted the timing of their breeding activities, but only by about 10 days. Sparrow hawks that prey on songbirds have been unable to keep pace with the changes in their songbird prey's life-cycle development. This asynchrony in timing of life-cycle events between the species means that the predator species is less able to take advantage of peak abundances of its prey. This in turn translates into decreased ability of the predator to provision its young during the breeding period, naturally leading to lowered offspring survivorship and population viability. This case example is not an isolated incident. Empirical synthesis of data on over 3000 terrestrial plant and animal species in the United Kingdom have revealed that in 30% of the cases, plant phenology has advanced by 6 days over the last 30 years, which is twice as much as herbivore and predator species (Thakeray et al. 2010).

4.17.3.3 Loss of Ecosystem Regulatory Capacity and Potential for Regime Shifts

Ecosystem models that do not consider food web interactions often predict that higher atmospheric CO_2 levels and temperature increases can enhance plant production, assuming water and nutrients such as nitrogen and phosphorus are not in limiting supply. The classic bottom-up view of ecosystem functioning would then predict that enhanced primary production should enhance the abundance of herbivore and predator species. However, evidence from field experiments spanning 15 years during which mean summer temperature varied by 2 °C and mean monthly precipitation ranged from 2.5 to 5 cm shows otherwise. Each year, experimentation systematically manipulated the food web composition of herbaceous plants, insect herbivores, and spider predators in a grassland ecosystem specifically to resolve and quantify the strength of bottom-up and top-down control in this grassland ecosystem (Barton et al. 2009). This research revealed that plant productivity was unaffected by temperature change or precipitation, but the strength of top-down feedback increased by 30–40% for every 1 °C rise in temperature. This again reinforces that there is asymmetry in the degree to which bottom-up and top-down effects penetrate food webs. This asymmetry arises in part because herbivore consumption rates of plants may increase with temperature, due to elevated metabolic demands for nutrients in warmer environments (especially for insects), and warming temperatures lessen the physiological constrains on daily feeding activity of vertebrate and invertebrate herbivores. Further evidence from a variety of invertebrate herbivore species shows the amount of plant biomass consumed can double with every 1 °C rise in temperature (Watt 1995; O'Connor 2009).

Forty years of annual data indicate that a cyclic weather phenomenon with a decadal trend in temperature, moisture, and winter snowfall – the North Atlantic Oscillation (NAO) – has a strong influence on the structure and functioning of a northern forest ecosystem comprised of wolves, moose, and balsam fir on Isle Royale, Michigan (Post et al. 1999). These changes in temperature and precipitation influence food web dynamics in ways that one might expect under a climate-altered world (Schmitz et al. 2003). For example, during part of the 10-year cycle, NAO forcing results in winters with anomalously warm temperatures and little snowfall – conditions expected and climate warming; while other periods are closer to the average current climate. Examining long-term dynamics over four, 10-year cycles provide a window into how longer term increases in temperature and reduction of snowfall might alter northern forest ecosystem functioning and services through alteration of food web interactions.

The study revealed that whenever snowfall levels are high (as in current conditions), wolves are extremely efficient predators of moose that are encumbered by deep snow. Consequently, wolves reduce moose populations to levels where they cause limited damage to balsam fir (Post et al. 1999). Thus, wolves exert important indirect top-down control over the compositional make up of forest vegetation through direct interactions with moose. The role of wolves becomes diminished when NAO forcing causes snowfall levels to decline, because it decreases the moose capture efficiency of wolves (Post et al. 1999). Over the long term, temperature increases and snowfall reductions could cause a cascade of effects including declining wolf populations, rising moose populations, and declining balsam fir productivity. Moreover, moose may increasingly suppress sapling tree recruitment, resulting in a more open forest canopy with a changed understory of shrub and herb species. Studies of moose-vegetation dynamics in other boreal forest systems indicate that browsing-induced reduction of canopy height and closure by even 12–50% results in higher light intensity, lower humidity, warmer and drier soils, and lower primary productivity of tree species (Schmitz et al. 2003). Thus, if moose are able to increase to such high abundances that the capacity of top predators to control prey abundances becomes severally diminished, the entire system may undergo a regime shift to a state of chronically low balsam fir abundance in the face of high moose abundance (Schmitz et al. 2003). Over the long term, bottom-up control can become increasingly dominant, such that soil chemistry can become altered through reductions in litter quality and rate of litter decomposition, causing a buildup of soil carbon that feeds from the bottom-up to exacerbate the reduction in ecosystem productivity (Schmitz et al. 2003).

Additional studies in this Isle Royale system support the idea that climate can induce ecosystem state changes through regime shifts. When disease struck and decimated the wolf population, moose were released from strong control by wolves (Wilmers et al. 2006). As a consequence, two factors, climate and abundance of fir trees, accounted for 60% of the variation in moose population abundance. In contrast, these two factors only accounted for 25% of variation in moose abundance before the disease outbreak and wolves accounted for 35% of the variation. Thus, viable populations of top predators in this system can help to buffer the effects of long-term alterations of weather patterns on ecosystem functioning. Ironically, however, persistent and chronic warming could disproportionately affect the very species that buffer the climate effects. Such is an example, both of the brittleness of the ecosystem service provided by predators and a critical tipping point that can lead to sweeping changes at the whole ecosystem scale akin to the grassland ecosystem example presented above.

4.17.3.4 Rewiring Food Web Networks due to Change in the Nature of Species Interactions

Food webs can become rewired when the lines of feeding dependency between species become fundamentally altered. This rewiring can trigger community disassembly leading to the loss of species; or it can cause reassembly in which species change their functional role in ecosystems. Thus, how climate may affect food web networks depends on whether it triggers disassembly or reassembly processes.

An example of climate-caused community disassembly comes from research in a grassland food web composed of herbaceous plants, a grasshopper insect herbivore, and spider predators which revealed that two different kinds of predators, a sit-and-wait ambush spider and an actively hunting spider, may have altered use of habitat, as well as change the nature of their interactions in response to alterations in the climate they live in (Barton and Schmitz 2009). The two predators normally segregate vertically in the vegetation canopy. The behaviorally dominant sit-and-wait spider resides in the upper canopy and the subordinate jumping spider resides in the middle to lower canopy. Grasshoppers roam widely throughout the canopy in search of food during the course of their daily activity, and so must run the gauntlet created by both spider species. Consequently, the level of mortality experienced by the grasshopper population is the average of the individual spider species effects. This averaging direct effect of the spider species on their shared prey results in an averaging indirect effect on the plant community composition, as well as, on ecosystem functions like nitrogen cycling and plant production. Experimentally, increasing the temperature of this system causes the sit-and-wait spider to move lower down in the canopy where it is cooler, causing it to overlap more with the jumping spider. This overlap, results in fierce interactions between the two spider species and ultimately the extinction of the jumping spider population in the experimental system due to predation by the sit-and-wait spider (a phenomenon known as intraguild predation) (Barton and Schmitz 2009). Community disassembly, due to the loss of the jumping spider predator species from the food web, can have ripple effects by transforming the composition and abundance of plant species in the food web, and in turn, affecting ecosystem functioning including a 30% decline in nitrogen mineralization rate and a 35% decline an aboveground plant primary productivity (Schmitz 2009).

Climate-caused community reassembly can also arise, if an introduced species changes the nature of species interactions among the existing members of the food web. A case in point concerns the reintroduction of wolves in Yellowstone National Park, United States, which, in turn, enhances the resilience of the ecosystem to changes in the park's temperatures. Prior to wolf introductions, species of scavengers including coyotes, wolves, ravens, hawks, and nine other species were subject to the vagaries of yearly variation in weather caused by ENSO events (Wilmers and Getz 2004; Wilmers and Post 2006). In particular, carrion is widely available during ENSO phases that lead to deep snow, and hence, heavy winter mortality of prey species such as elk. ENSO can result in regional increases in temperature and less snowfall, thereby reducing lowers winter prey mortality. Thus, carrion for scavengers, particularly those with strong seasonal patterns in resource use, like grizzly bears, is reduced (Wilmers and Getz 2004). This, in turn, affects the viability and abundance of the scavenger species. The insertion of the wolf into the food web via reintroduction seemed to have enhanced the resilience of the food web by buffering the ENSO effects. Wolves are able to hunt year-round. The establishment of a predator–prey feeding link between wolves and prey like elk meant that there would be a steady supply of carrion to the scavenger species among seasons and years. Wolves may increase the resilience of this ecosystem by causing a crucial food resource in the food web to be controlled by a more constant biotic rather than variable abiotic factor Wilmers and Getz 2004; Wilmers and Post 2006).

4.17.4 Possibilities for Climate Effects to Alter Ecosystem Function

The case examples presented here were chosen because they offer solid evidence for the kinds of ecosystem effects that can be realized through climate effects on food webs. The scientific evidence comes from two kinds of sources: observational studies that track interannual variation in abiotic conditions (temperature, precipitation, etc.) and manipulative experiments that alter abiotic conditions. The experimental studies often push abiotic conditions to a 3–5 °C rise in the temperatures experienced by the study area, which is felt to be a plausible possibility in the coming decades. This portends future community disassembly that could cause regime shifts and significant (e.g., 30–40%) reductions in levels of ecosystem functioning and services. These effects come about because top predator species are important determinants of ecosystem resilience to climate, but at the same time, are the species most sensitive to human impacts on food webs through resource exploitation.

These examples highlight the potential for the functional role of upper level species (especially predators) to be more brittle (less resilient) than that of species (e.g., plants) lower down in the food web. In many cases, the implications of climate effects on terrestrial food web interactions have yet to be empirically traced to ecosystem functioning. Thus, it remains altogether uncertain what effects predator loss will have on production of natural resources in ecosystems in the future.

The current inability to assess the likelihood of the different kinds of outcome illustrated above arises from two limitations with our scientific understanding. First, empirical case studies are insufficient in number to conduct meta-analyses that assess likelihoods of outcome. Second, the reliability of estimated future conditions using food web and ecosystem models is heavily dependent on accurate understanding of biological conditions that form model assumptions, as well as accurate estimates of parameters that drive the model dynamics, including how well climate models can predict the spectrum of possible future local and regional climate. Again, our empirical understanding of the range of climate effects on food webs and ecosystems is insufficient to constrain the range of model parameter values. Thus, it is impossible at this time to offer general conclusions.

4.17.5 Policy Actions to Minimize or Eliminate the Negative Consequences of Climate Effects

The scientific community has amply demonstrated that changes in local and regional climate statistics could reorganize communities and associated ecological systems across landscapes because species existing within a community would not respond in the same way to this stressor. Some species may tolerate the climate stressor. Others may shift their geographic ranges, but, nevertheless, may not move en masse to new locations, leading to community disassembly. Moreover, new species migrating from other regions may enter a food web and forge new dependencies with the local species leading to community reassembly. Yet, much of the focus in natural resource conservation and management is still on single species or single resource stocks that have particular value for stakeholder groups.

A practical start to addressing climate effects on food webs and ecosystems is to begin recognizing that the processes of community disassembly and reassembly means that focusing on single species or resources when planning for climate adaptation will provide incomplete solutions (**Figure 1**). The scientific lessons presented here are that conservation and management must take a broader food web perspective and change its conception of the important factors controlling ecosystem functioning. A food web perspective highlights that species do not exist in isolation but rather belong to larger communities based on common habitat, resource, and thermal needs. It then logically follows that species in ecosystems may not simply be a product of available production within an ecological system (bottom-up control), but may also be integral and active players determining how the ecological systems function (top-down control). This perspective embraces modern scientific understanding about species' functional roles in nature. Moreover, a food web perspective can help reason through how important dependencies among species might become uncoupled, as well as understand the potential fate of species that are important to the provision of ecological services. Species within food webs are interdependent with each other and may provide important ecological services because of those interdependencies, not in isolation of them (**Figure 1**).

4.18.1 Introduction: Scope and Scale

Tourism is an ambiguous term that refers both to a commercial industry and to a category of human behavior, with all the associated psychological, social, and economic incentives and constraints. From the industry perspective, which includes government tourism portfolios and economic statistics agencies, tourism is generally defined as overnight travel more than 40 km from home, for purposes which are personal rather than work-related. This is a definition of convenience that includes some rather blurred and arbitrary boundaries, but it is useful for statistical purposes. From a social perspective, any individual's time can broadly be divided into work, home, and play, i.e., employment, domestic, and leisure. Recreation is one component of leisure, and tourism is a type of recreation that involves travel.

In practice, tourism usually involves the purchase of commercially provided products specifically for that particular holiday journey. Such products are generally divided for convenience into transport, accommodation, and activities. A family that drives 100 km in its own car, camps overnight in its own tent, and eats food that it brought from home would probably think of this activity as recreation rather than tourism, but would nonetheless technically be treated as tourists in statistical terms. Similarly, many recreational activities, commercial or otherwise, are available to and equally enjoyed by locals and visitors alike. Examples include hiking in a national park, surfing or sunbathing at the beach, or going as a spectator to a musical or sporting event.

Estimates of the economic scale and social significance of tourism and recreation thus depend on just what is included. International tourist air travel, for example, is routinely recorded with reasonable precision, and aggregate figures are compiled and annually published by the UN World Tourism Organization (UNWTO). In many countries, however, domestic tourism is far larger in scale than international: up to two orders of magnitude larger, for example, in countries such as China and India. In addition, the relative scale of domestic and international tourism depends on the size of the countries concerned. A distance that represents an international journey in Europe, Central America, or Southeast Asia would be domestic travel in the United States or Russia. Ignoring these statistical distortions, UNWTO (2011) reported almost one billion international tourist arrivals in 2010, representing an annual expenditure of close to one trillion dollars.

The economic scale of domestic tourism and recreation is more difficult to gauge accurately. Fully packaged tours, which include the costs of labor, catering and consumables, and recreational equipment rental as well as transport and accommodation, make up only a small proportion of total domestic travel, generally less than 15%. For the remainder, people use the same vehicles that they also use at work and at home, they use the same recreational equipment that they may also use after work or at the weekends, and they rely on their own labor rather than paying anyone else. They may stay in a relative's house, a holiday house, or a second home. Whether this involves walking from one mud hut to another or taking a private helicopter to a palace, it rarely involves commercial transactions that can be tracked by economic statisticians.

Instead, economic estimates for these components involve partitioning the size and scale of the sporting goods market, the property market, and the automobile market, and assigning a value to individual unpaid time. As in all industry sectors, there is also an economic multiplier effect in tourism-dependent communities, as people employed in the tourism sector locally spend their earnings. Taking these factors into account, the World Travel and Tourism Council (WTTC), tourism's peak international industry association, estimates the global economic scale of tourism as USD seven trillion, almost an order of magnitude higher than the UNWTO estimate. Estimates from other sources indicate that outdoor recreation in the United States alone is worth USD 852 billion, approaching the trillion-dollar estimate provided by UNWTO for the entire international tourism sector.

Perhaps more important than the absolute economic scale of the tourism sector is its position relative to other sources of revenue, in particular countries and communities. Worldwide, tourism is estimated to contribute 9.1% of global Gross National Product (GNP), and >10% of global employment (WTTC 2011). Similar figures apply at national scale for large and wealthy developed nations with mixed economies. For a number of smaller nations, however, particularly in the developing world, tourism is a much more significant economic sector.

In particular, there are at least 50 nations where tourism provides the largest single source of foreign exchange, essential if governments need to purchase equipment not locally available or if companies need raw materials not available in the country concerned. Commercial tourism, particularly international tourism, has thus become a significant contributor to economic well-being in a number of countries and rural communities; but equally, this dependence makes them vulnerable to any disturbance or downturn in inbound visitation rates. Of course, such international dependencies are by no means restricted to the tourism industry. They do, however, add an extra complexity in calculating the vulnerability of tourism and recreation to climate change.

4.18.2 Components and Sources of Vulnerability

In examining the vulnerability of tourism and recreation to climate change, we can consider three distinct though tightly cross-linked components. The first is the tourists, that is, the people who plan to play, whether close to home or far away. The second is the destinations: the places they want to visit. The third is the enterprises, the many tourism-related businesses that help to get the tourists to their destinations and look after them once they arrive.

Changes to any one of these components will commonly also affect the others. If a destination becomes relatively more or less attractive to tourists, because of local effects of climate change, that will influence the number of tourists arriving there, unless the various enterprises involved can successfully market different or changed attractions at the same destination. If people from a particular country or region travel more or less because the climate at home has changed, that will affect the destinations they travel to and the enterprises they travel with. If the cost of a particular travel-related service increases because of climate-related effects, and fewer tourists purchase that service as a result, then the enterprise providing the service may change what it has to offer, with consequences for tourists, destinations, and other enterprises.

In examining the vulnerability of tourism and recreation to climate change, therefore, we need to consider all three of these components and also the links between them. We start by examining direct physical effects of climate change on tourist destinations, and the degree to which these can be counteracted by engineering approaches, exacerbated by changes in social institutions, or outweighed by changes in tourism product portfolios and marketing strategies. Next, we consider the various factors that influence when, where, and how much individual tourists travel, and how these will be affected by climate change. Finally, we consider how tourism enterprises can adapt to such changes in tourist behavior, and how changes in tourist behavior and destination attractiveness will affect different subsectors of the commercial tourism industry.

Like most industry sectors, tourism contributes *pro rata* to greenhouse emissions and consequent climate change, particularly through longhaul air travel. Like most primary industry sectors, but unlike most secondary and tertiary sectors, the tourism industry is also highly vulnerable to the impacts of climate change. As outlined above, this includes both direct physical changes at tourist destinations and recreational sites, and indirect changes in travel and activity patterns caused by the increasing financial and possibly also social costs of holiday travel. In line with the theme of this volume, this chapter examines only how tourism and recreation are affected by climate change, not how they may contribute to it.

4.18.3 Destinations

Even at a global scale, predictions of key climatic parameters, such as temperature, rainfall, sea level, and so on, still remain somewhat uncertain (IPCC 2007; Parmesan and Yohe 2003). At the regional and local level relevant to tourism and recreation, there are few fine-scale predictions for critical parameters, and most of these indicate high levels of uncertainty. Early models, for example, predicted increased storminess for the tropical east coast of Australia, whereas more recent models predict less storminess but a more acid ocean with impacts on coral reefs (Hoegh-Guldberg et al. 2007). In addition, predictions are that in many regions, several climatic parameters will change simultaneously. Many montane areas, for example, are expected to experience increased temperatures coupled with reduced rainfall, and both of these reduce snow cover (Pickering and Buckley 2010). Reduced snowfall, especially at lower altitudes, affects ski tourism destinations in many countries (Scott and Seiger 2013; Agrawala 2007; König and Abegg 1997).

Especially where several primary climate parameters change simultaneously, these changes can generate a chain of secondary consequences. In woodland areas, for example, a combination of raised temperatures and reduced rainfall is likely to increase the frequency and intensity of fires (Buckley 2007) and may extend the length of the fire season (Lucas et al. 2007). In low-lying coastal areas, more intense low-pressure weather systems could create both heavier rainfall and increased storm surge due to low atmospheric pressure, producing more widespread flooding in urban areas and increased erosion on some rural coastlines (Buckley 2007).

Commercial tourism development, especially at large scale, also needs large volumes of water. In many countries, water supplies are already limited and subject to intense competition from other industry sectors. If rainfall decreases or becomes more irregular, or temperature and evaporation increase, or both, then water availability will decrease and water prices will increase. This is already the case for many of the world's coastal tourism destinations.

Changes in seasonal and diurnal temperature patterns in rainfall and groundwater, and in fire and flood regimes, can all influence vegetation and wildlife (Klanderud 2005). Indeed, the geographic distribution and annual life histories have already changed in response to climate change for many hundreds of plant and animal species (Root et al. 2003). Any change for any one species, either in space or time, can have consequent impacts on others.

These patterns are commonly quite complex and difficult to predict. Many species exist in balance not only with their physical environments, but with each other. They may compete for space or resources, or rely on each other for food or dispersal. Under such circumstances, even quite a small change in the climatic, physical, or biological context for such interactions between species can generate a greatly amplified response. Long-term ecological research has shown that the boundaries of adjacent patches of different vegetation can move back and forth over time as they compete for space, with the relative advantage depending on weather patterns. Under climate change, the historical balance may be permanently altered in favor of one or other of these plants. This affects all the associated plant and animal species, including those significant for commercial tourism.

As another example, many species of birds worldwide time their nesting periods to coincide with a large-scale spring emergence of insects, which they use to feed their nestlings. There are already a number of cases where, as a result of climate change, the insects have hatched earlier in the year (Roques and Robinet 2010) and the birds have gone hungry. Once again, given the increasing economic scale of the birdwatching tourism sector worldwide, anything that changes the opportunities for tourists to see particular species may have economic and social as well as environmental consequences.

Further complexities and consequences arise because of the interactions between physical and biological changes, and human social factors. This includes both individual human behavior, and social structures and institutions such as land tenure and land use patterns, taxation systems, and travel patterns. For example, if tourists have historically been able to watch individual icon wildlife species in particular national or marine parks, either year round or seasonally, but because of climate change those species no longer survive or migrate there, that will affect any commercial tourism product based on seeing those species. Such concerns are particularly well-known for polar bears, notably for the bear-watching industry of Hudson Bay in Canada (Stirling and Parkinson 2006; Dawson et al. 2010), but they may equally apply to many other species.

Similarly, if land management agencies close access to particular areas because of increased fire or flood risk, and/or open access to new areas, then those changes will affect any tourism enterprises whose products rely on such access. Agencies may also allow continued access for some purposes, but place restrictions on particular activities that were previously permitted. This applies to public lands such as national parks and forests and also to private land, and it has already occurred in some regions. Kosciuszko National Park in Australia provides an example.

There may also be indirect social changes at destinations. If reduced or increased attractiveness or access changes demand or availability at particular destinations, affecting the number of visitors arriving, then this may also affect the attitudes of residents to tourists, and the prices and availability of tourist services and infrastructure offered.

4.18.4 Tourists

Changes at destinations modify their attractiveness to tourists, also known as the 'pull' factor. Climates are also simultaneously changing in tourists' countries of origin. Tourism is driven in part by the attractiveness of a holiday destination relative to home. Changes at home, the 'push' factor, can thus also alter this balance (Crowe 1975; Bigano et al. 2006; Hamilton and Lau 2005; Lise and Tol 2003; Eugenio-Martin and Campos-Soria 2010; Hall and Higham 2005).

The most critical climate changes are those that affect the least attractive season at home. If cold-country winters get colder or hot-country summers more (or less) humid, for example, that influences what residents do for leisure and recreation both locally and by traveling. They may shorten or lengthen the season for particular recreational activities, or add or substitute different activities; or they may travel more, or less, or to different places for either the same or different types of leisure and recreation (Wall 1992). All of these preferences and behaviors may differ between different ethnicities, socioeconomic statuses, and individual backgrounds.

In addition to changes in both push and pull factors for people to travel as tourists from and to particular places, their travel decisions are also influenced by the cost and convenience of transport options (Tol 2007; Peeters and Dubois 2010; Buckley 2011a). Demand for holiday travel is currently quite inelastic to price (Tol 2007; Buckley 2011a,b); but as carbon taxes or tradeable permit systems, coupled with rising fuel price, increase air travel costs, people may change the pattern, distance, frequency, or mode of holiday travel. This, however, depends on availability. People can only switch from plane to train if trains actually exist. And if people want to bring bicycles instead of hiring cars at their destination, they can only do so if the plane or train makes this simple and cheap (Dickinson et al. 2010, 2011).

It is also possible that travel patterns may be changed through social pressures as well as prices. To date there is little evidence of this: people continue to travel on holiday, even if they are aware of their climate change impacts; and they provide various social justifications for doing so (Buckley 2011a,b; Dickinson et al. 2010, 2011; Gössling et al. 2007; Dawson et al. 2010; Becken 2007). Some tourist destinations aim to counteract any negative social perceptions of longhaul travel through large-scale carbon offset programs, so as to become 'carbon neutral' (Gössling and Schumacher 2010). These programs have limited credibility at present (Gössling et al. 2007; Anderson 2012; Edwards et al. 2011).

These factors may or may not change as the world's wealth shifts between nations. Currently, a high proportion of long-haul air travel is attributable to a relatively small number of so-called hypermobile travelers, mainly from North America and Europe. As citizens of the BRIC nations – Brazil, Russia, India and China – become increasingly wealthy and want to travel more, it will be their social attitudes that influence travel patterns. These are less studied and are rapidly changing.

4.18.5 Enterprises

The ways in which individual commercial tourism enterprises are likely to be affected by climate change, and the ways in which they can adapt, depend strongly on the types, structures, and locations of the enterprises concerned. Companies that act principally as packagers or agents, whether outbound or inbound, are likely to be least affected. If particular destinations or activities become less attractive to tourists as a result of climate change, these companies can simply substitute alternative places and products, and so continue to retain or expand their client base.

The same applies for companies that offer a single activity at many different destinations. Different degrees of change may be needed, depending on the type of activity offered. Activities that take place in urban or other man-made environments, such as golf courses, will probably continue to operate unabated at the same locations as currently; though costs may increase or decrease to reflect the changing prices of, for example energy and water.

For activities that rely on a natural attraction in a built or urbanized setting, such as ski and beach resorts, engineering adaptation to climate change is feasible in the short term (GBRMPA 2009; Hallegatte et al. 2011). In the medium term, factors such as reduced snowfalls or water supply, rising sea levels, or increasing incidence of disease, are likely to make particular destinations relatively more or less attractive in the future (Buckley 2008a,b; Scott and Seiger 2013).

For destinations that are already large and well-known, substitution between activities is also possible, for example, from winter skiing to summer golf, or from ocean bathing to swimming pools. For activities that are completely dependent on the natural environment, such as whale watching or whitewater rafting, sea kayaking or game safaris, a much greater degree of substitution may be required, since particular attractions or activities may become completely unavailable in some areas that were previously popular.

Tourism enterprises that offer only a single activity at a single destination are potentially most vulnerable to climate change; though again, vulnerability may greatly differ between destinations and activities. If melting of the Arctic sea ice means that polar bears no longer visit Hudson Bay in northern Canada, for example, then the companies that currently offer tours to watch them from the heated giant-wheeled buses known as tundra buggies, will completely lose their clientele. On the other hand, the same melting of Arctic sea ice makes new areas accessible to cruise ships.

Likewise, if the increasing risk of summer bushfires in the dry eucalypt forests of Australia's Snowy Mountains means that the park management agency restricts overnight camping during the summer months, then a local farm that offers multiday horse riding tours into the park, with overnight camps and campfires in 'The Man from Snowy River' style (Ollenburg 2006), might still have clients but nowhere to take them. A company that offers artistic or retail attractions at an urban venue, however, is likely to be little affected by climate change as long as tourists still visit the town concerned.

Tourist enterprises are in any event constantly adapting and readapting to match the interests of potential clients to the possibilities of particular destinations. They will feel the effects of climate change both through changes at destinations, as outlined above, and through changes in the behavior of individual tourists. These are very difficult to predict because they involve the interaction of several quite different factors.

Changes in the features of particular destinations and products on offer, as outlined above, do not operate independently. There are also changes in climate at major countries of origin, which affect the relative attractiveness of different potential ways to spend one's vacation time. There may be quite large-scale changes in the financial costs and social context for holiday travel, especially longhaul international air travel. In addition, travel patterns are heavily dependent on the relative distribution of wealth, on cultural differences between countries, and on the ever-fickle effects of fashion. All of these overlay, and may outweigh, the effects of climate change, so that the latter are difficult to detect reliably.

4.18.6 Most Vulnerable Subsectors

The ski industry is particularly vulnerable to warming and to reduced precipitation, since these changes reduce both natural snow cover and opportunities for snow making. Ski resorts in North America and Europe, Australia, and New Zealand are much more vulnerable than those of Hokkaido in Japan or those of northern Canada and Alaska (Agrawala 2007; König and Abegg 1997; Scott and Seiger 2013). The industry's response to date has been to increase snow making, snow grooming, and terrain modification; to reposition resorts from winter to four-season; and to increase financial reliance on property and retail rather than lift tickets (Pickering and Buckley, 2010).

The coastal resort industry has responded to climate change much more slowly than ski resorts (Buckley 2008a). Possible reasons include lags in oceanic as compared to atmospheric changes; more distributed ownership of land and infrastructure in coastal settlements; controversy over liabilities and responsibilities; and misperceptions of likely climatic impacts (Buckley 2008a). Tourists seem to be more concerned with esthetic appearance, whether natural or man-made, than with erosion or coastal processes *per se* (Buckley 2008a; Moreno and Becken 2009; Buzinde et al. 2010).

Tropical coral reefs are susceptible to bleaching from warm ocean temperatures (Burke et al. 2011), but to date this seems to have had relatively little effect on tourism (Lasagna et al. 2010). Many of the world's reef tourism destinations have experienced bleaching events, but the only serious effect on visitation so far seems to have been a 9% drop at Palau (Glantz 2000, cited in Becken and Hay 2007). Experienced divers descend below the impacts of bleaching, and snorkellers seem unconcerned as long as they can still see fish. Future effects may be more severe if the ocean becomes increasingly acid (Hoegh-Guldberg et al. 2007).

Low-elevation tropical and subtropical oceanic island destinations are especially vulnerable to sea level rise, increased storminess, degradation of coral reefs, and increased costs of longhaul air travel. To date, there has been limited impact on tourism revenue, since these destinations have simply adopted more heavily engineered forms of development, which they were moving toward in any event so as to increase capacity, safety, and levels of luxury.

Higher-elevation bedrock islands, whether at high or low latitudes, are less concerned over physical changes and more over potential losses in visitation due to increased travel costs. The Azores, for example, has complained that European Union carbon taxes on air travel are affecting its tourism economy. The Seychelles has claimed that it will reposition itself as a 'carbon neutral' destination, but this seems likely to be merely a marketing claim designed to assuage the consciences of its wealthy international visitors.

In forested destinations, the main risks of climate change are from increased wildfires, which damage infrastructure and affect both access and attractiveness for tourism. In grasslands and deserts, droughts will affect populations and migrations of icon watchable wildlife species, as well as grazing pressure from domestic livestock, cultural landscapes, and the availability of water. None of these have yet been analyzed at significant scale and detail from a tourism perspective.

4.18.7 Priorities for Future Research

Three major themes are immediately apparent as priorities for future research to assess and minimize the vulnerability of tourism and recreation under climate change.

The first theme principally applies to urban tourist destinations and large-scale resorts. For these, the key issue is the degree to which market share can be maintained by modifying the mix of activities and attractions. This is essentially a question of tourist behavior, and there is already a considerable body of academic literature on tourism economics and geography, marketing and market research, and destination lifecycles that could be adapted to examine this question.

The second major theme is that of extreme weather events: their immediate impacts on tourist safety, attractions, and infrastructure, and their longer-term effects on competition between destinations. There is already a significant academic literature on disaster response and crisis management in tourism, which can be applied here.

The third, and perhaps most complex research theme, is in predicting how natural attractions for tourism may be modified by climate change and how tourists may change their travel patterns accordingly. This theme covers not only direct impacts of climate change on parks and beaches, water and wildlife, but also the indirect impacts on tourism as the social frameworks for access to these attractions change in response to changing climates (Buckley 2007).

4.18.8 Conclusions

Climate change is indeed a highly significant issue for the global tourism industry: less acute than wars and terrorism, but larger scale and longer lasting. The subsectors of the tourism industry most affected by climate change will be smaller fixed-site operators or destinations that heavily rely on a single natural attraction, such as snow, reefs, or wildlife, that happen to be particularly susceptible to climate change. Even in these cases, however, there are opportunities to reposition either the product or the target market segment so as to maintain revenue. The key in these cases will be forethought and innovation to maintain a competitive position as corresponding adjustments occur worldwide.

Climate change is likely to become so pervasive that it should be mainstreamed into all aspects of tourism research. To some degree, this has already happened (Hall 2008; Hall et al. 2011; Schott 2010; Scott et al. 2007; Weaver 2011; Scott and Seiger 2013). Already, many analyses in tourism economics routinely refer to various climate change scenarios in much the same way as they routinely specify discount rates. Future research in tourism planning, policy, and geography will no doubt refer to regional climate change patterns and predictions in a similar way.

In the short term, however, it would seem that if we were to pick a single top priority for research, it would be the social and environmental consequences of extreme weather events at destinations, and the flow-on effects for tourism.

4.19.1 Introduction

The world is currently experiencing a suite of environmental changes (see Section 4.19.2, this volume), which are causing rapid declines in biodiversity. In addition to the moral tragedy of this loss, there is growing concern that biodiversity loss may negatively affect the way in which ecosystems function, and the services that these functions provide. Since a number of seminal studies in the early to mid-1990s (e.g., Naeem et al. 1994; Tilman and Downing 1994; McGrady-Steed et al. 1997), there has been a growing consensus that biodiversity is generally important for the maintenance and stability of ecosystem functioning (Chapin et al. 2000; Hooper et al. 2005; Díaz et al. 2006), though there are a number of case studies showing no effect, or even a negative effect of biodiversity on the rates of certain ecosystem functions or processes (Rodriguez and Hawkins 2000; Finke and Denno 2004; Srivastava and Vellend 2005). Therefore, rather than simply asking 'does biodiversity affect ecosystem functioning', understanding the context under which biodiversity is important has become a major issue, which we will discuss below. Biodiversity effects will also occur within the context of direct effects of environmental changes on ecosystem functioning, and disentangling the relative importance of these pathways will be a major challenge for the future (Huston and McBride 2002). Therefore, we will discuss these direct versus indirect pathways, and how establishment of their relative impact may determine the most effective approach to managing ecosystem services in a changing environment, as well as the circumstances under which conservation of biodiversity will bear the greatest impact on ecosystem functioning.

Despite this uncertainty regarding the importance of biodiversity relative to the direct effects of environmental changes on ecosystem functioning, there is growing appreciation that multiple drivers may have non-additive impacts, such that the overall effects on ecosystems cannot be predicted from the effect of each driver in isolation. This is being increasingly (albeit slowly) recognized as important for biodiversity loss and threatened species management (Didham et al. 2007; Brook et al. 2008). However, the nonindependence of multiple drivers has not been well incorporated into the literature examining biodiversity effects on ecosystem functioning. The distinction is probably symptomatic of the disconnect between studies examining the causes of biodiversity loss, which increasingly recognize interactions among multiple drivers (Didham et al. 2007; Brook et al. 2008), and studies examining the consequences of reduced biodiversity, which usually simulate random species losses in experiments, without inferring any particular driver or drivers of this loss (Srivastava and Vellend 2005).

Nevertheless, real world extinctions are not random, but rather depend on characteristics (traits) of individual species (e.g., Lavorel et al. 1997; Lavorel and Garnier 2002; Larsen et al. 2005). Thus, individual drivers of global change may select for species with certain responses to a given stressor (e.g., 'response traits', Elmqvist et al. 2003), which may in turn be related to their contribution to ecosystem functioning (e.g., their 'effect' traits, (Lavorel and Garnier 2002; Larsen et al. 2005), Figure 1). We will discuss how environmental changes such as climate may select for certain functional traits, and how this may generate strong interactive effects on ecosystem functioning. Finally, we will draw overall conclusions about the cumulative threat to ecosystem functioning posed by a suite of environmental changes, and highlight areas in need of future research.

4.19.2 Direct and Indirect Effects of Environmental Change on Ecosystem Functioning

As mentioned above, there can be important indirect effects of environmental changes on ecosystem functioning, mediated through the loss of biodiversity (Figure 1, see also the chapter

http://dx.doi.org/10.1016/B978-0-12-384703-4.00432-9

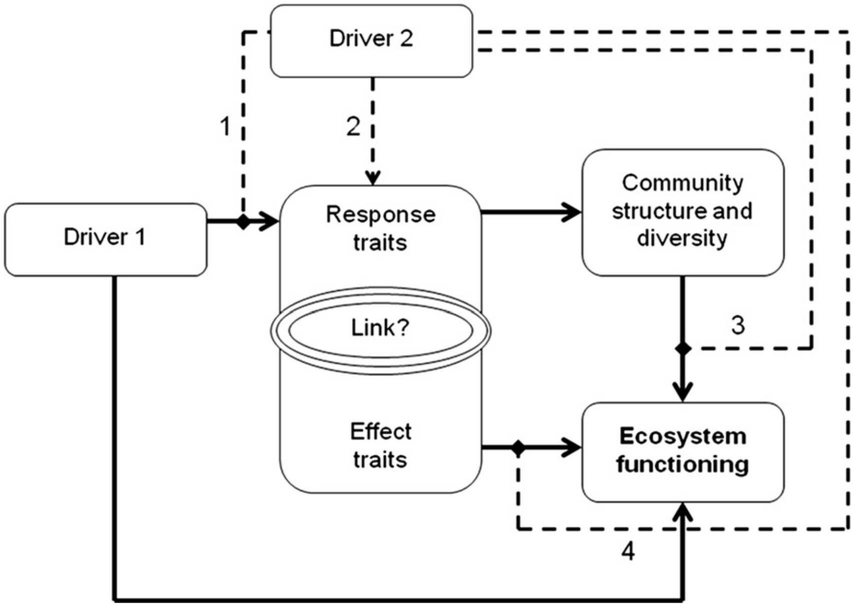

Figure 1 Direct and indirect pathways through which two drivers of environmental change can interactively affect ecosystem functioning. Arrows indicate direction of effect; dots within arrows indicate that the effect pathway is moderated by another driver. Solid lines indicate the direct and indirect effects of Driver 1, whereas dashed lines (paths 1–4) indicate the additional effects of Driver 2. The latter include **path 1**: Driver 2 changes the trait optima selected by Driver 1, **path 2**: Driver 2 selects for different trait optima, **path 3**: Driver 2 moderates the diversity–function relationship, **path 4**: Driver 2 moderates how specific trait combinations affect ecosystem functioning. In these cases, drivers could be weather-related variables (temperature, precipitation, heat waves), atmospheric composition and pollution (CO_2 concentration, nitrogen deposition), species invasions, or land-use change (fragmentation). Adapted from Figure 1(c) in Lavorel, S., and E. Garnier, 2002: Predicting changes in community composition and ecosystem functioning from plant traits: revisiting the holy grail. *Funct. Ecol.*, **16,** 545–556.

of Kittel, this volume). However, in addition to indirect biodiversity-mediated effects, all environmental changes may themselves have direct impacts on ecosystem functioning (Figure 1). For example, facets of agricultural intensification obviously have direct effects on functions such as biomass production (the ‘Green revolution’ of the mid-to late twentieth century demonstrated this comprehensively), and nitrogen deposition may enhance rates of decomposition (Manning et al. 2008). Even when species diversity is unaffected, changes in the abundance of a functionally important species may alter ecosystem process rates. For example, habitat fragmentation (both increased isolation from natural habitat and reduced area of habitat within the landscape) has been shown to reduce bumblebee abundance, which led to reduced pollination of tomato crops (Greenleaf and Kremen 2006). Thus, even in the absence of indirect biodiversity-mediated effects, environmental changes can impact ecosystem functioning directly.

That environmental changes have these kinds of direct effects on ecosystem functioning should come as no surprise. However, more surprising is the paucity of research addressing the relative importance of biodiversity loss (an indirect effect on ecosystem functioning) versus direct effects of the environment on functioning (Huston and McBride 2002), and how this relative importance may vary across systems. Importantly, this balance will determine the utility of different management approaches for maximizing ecosystem services. For example, if the effects of biodiversity loss on functioning are minute relative to the direct effects of these human impacts, then the functional argument for species conservation would be weakened.

Based on observations of natural patterns of productivity and species richness, it has been suggested that biodiversity can play only a minor role in functions such as primary productivity, which are instead driven primarily by environmental (abiotic) conditions (Huston 1994; Huston and McBride 2002). This tenet has recently been tested in a study that used a ‘response-effect trait framework’ (Lavorel and Garnier 2002; Suding et al. 2008; see below) and structural equation modeling to determine the direct and indirect effects of two components of land-use change (experimental fertilization and grazing intensity) on biodiversity and ecosystem functioning (Laliberté and Tylianakis 2012). After more than 20 years of simulated grazing and fertilization treatments, composition and diversity of the plant community had changed considerably, with consequences for several ecosystem functions. This work found that functional trait diversity in plant communities affected aboveground primary productivity, and that productivity was positively related to other ecosystem functions such as leaf decomposition and soil carbon sequestration (Laliberté and Tylianakis 2012). These results support the results of the previous biodiversity experiments (discussed above) that assume random species loss, and confirm the importance of primary productivity as an aggregate measure of community functioning. However, the effect of functional trait diversity on productivity only became positive under conditions of high soil resource availability; for example fertilization moderated the biodiversity effect (see next section). Most importantly, the direct effect of soil resources (and to a lesser extent of grazing intensity) on all the ecosystem functions measured was far greater than the indirect effects mediated via biodiversity loss or changes in the trait composition of the plant community (Laliberté and Tylianakis 2012).

This result is somewhat intuitive, as many of the most productive ecosystems on earth (e.g., agricultural crops, forestry plantations) have low biodiversity (Huston and McBride 2002), and it is the primary driver of this biodiversity loss (land-use intensification) that itself maintains the high rates of productivity. Thus, selection of species for agriculture that produce high yields, combined with external inputs such as nutrient fertilizers, has to an extent uncoupled biodiversity from ecosystem functioning in many anthropogenic systems. This may explain the apparent paradox that humanity is receiving increasing ecosystem services at the same time as biodiversity is declining (Raudsepp-Hearne et al. 2010), and emphasizes that functional degradation of ecosystems may be masked by external inputs that cannot necessarily be sustained in the long term.

These broad issues of the timescales over which biodiversity is important, and the long-term sustainability of functioning, must be incorporated into any assessment of the Earth's vulnerability to environmental change. In particular, the selection of certain kinds of species by one environmental change driver may affect the resilience of the system to other drivers (discussed below). Finally, the above work illustrates that we should not expect to see general patterns in the effects of biodiversity loss across all systems, but rather, we must understand the conditions under which biodiversity loss will have its greatest impact.

4.19.3 The Importance of Environmental Context for Biodiversity Effects on Functioning

In addition to the direct effects of environmental changes on ecosystem functioning, and the indirect effects mediated through biodiversity loss, environmental changes may even moderate the importance of biodiversity for ecosystem functioning (**Figure 1** pathway 3). One of the main mechanisms underpinning a positive biodiversity-ecosystem functioning relationship is niche complementarity (Loreau et al. 2001), whereby different species utilize different resources, or the same resources are obtained in different ways. This reduces interspecific competition relative to intraspecific competition, and allows more complete utilization of the available resources, thereby maximizing functioning at the community level. Clearly, for complementarity to operate, two requirements must be met. First, different species must occupy different niches or functional groups (Loreau et al. 2001; Wardle and Zackrisson 2005). Second, there must be a range of niches available to be partitioned among the species, or in other words, there must be a heterogeneous resource base (Tylianakis et al. 2008b).

The ecosystem function receiving the most attention in the literature, plant biomass production (possibly because of its link to ecosystem services such as carbon sequestration and pasture production, and because it can correlate with other functions, see above), provides a clear example of this phenomenon. Complementarity among plant nutrient acquisition strategies, which could potentially make diverse plant assemblages more productive, requires heterogeneity in resources such as soil nutrients. Differences in soil heterogeneity may therefore have blurred the effects of biodiversity in some experiments, and created contrasting experimental results across regions (Huston and McBride 2002).

The importance of soil nutrient heterogeneity for moderating biodiversity effects was tested explicitly in German grasslands, using structural equation modeling of observational data (Tylianakis et al. 2008b). It was found that plots with more heterogeneous soil resources had a stronger relationship (i.e., a more positive slope) between plant biodiversity and biomass production (belowground biomass in this case). It was argued that heterogeneous soil resources created a greater variety of niches to partition, which could be better exploited by diverse plant assemblages than by those that were species poor. This premise was supported by similar evidence from experimental studies (Weis et al. 2008). In addition to plant biomass production, results from Indonesia and Ecuador showed that the relationships between diversity (of pollinators or parasitoids, respectively) and functions (pollination success and host attack rates) also became stronger with increasing heterogeneity (patchiness) in the availability of the resource being partitioned (flowers and hosts, respectively) (Tylianakis et al. 2008b; Weis et al. 2008).

Finally, in addition to resource heterogeneity being important, the total amount of available resources may moderate the effect of biodiversity on ecosystem functioning. Of course, resource availability may alter rates of competitive exclusion, thereby determining local biodiversity in the first place (Huston 1994). However, experiments have shown that, like heterogeneity, resource availability may moderate the diversity–function relationship, which becomes increasingly positive as resource availability increases (Fridley 2002; Boyer et al. 2009; Laliberté and Tylianakis 2012). In terms of ecosystem services, Laliberte and Tylianakis (2012) note that these findings support the importance of diverse species mixtures for maximizing the efficiency of high-input production systems, such as pastures (Sanderson et al. 2004) or biofuel crops (Fargione et al. 2008).

Combined, these results suggest that environmental context (such as resource availability and heterogeneity) plays an important role in moderating the effect of biodiversity on ecosystem process rates, and this hypothesis can be applied to any ecosystem service for which biodiversity is important. For example, diverse predators (control agents) may improve the success of biological control (Snyder et al. 2006), though this benefit may only occur under certain circumstances (Tylianakis and Romo 2010). However, these results carry an even greater importance within the context of environmental change. For example, increased climatic variability may generate greater temporal heterogeneity in the availability of resources (such as prey for predators, or flowers for pollinators), which could make biodiversity more important for maintaining ecosystem functioning. In contrast, other environmental change drivers (such as land-use change or nitrogen deposition) may homogenize basal resources, potentially reducing the benefits of biodiversity, or increase resource abundance, with the opposite effect. Thus, any change can potentially have direct effects on ecosystem functioning, indirect effects mediated through biodiversity loss, and even potentially moderate the relationship between biodiversity and ecosystem functioning (**Figure 1**).

Nevertheless, the biodiversity-mediated effects of environmental change on functioning may depend largely on the kinds of species that survive in the face of each change driver. The contribution of each species to ecosystem functioning, as well as the potential for complementary niche partitioning, will ultimately depend on the traits of each species present in the community. Accordingly, functional traits, and more specifically functional-trait composition and diversity within assemblages, are now widely recognized to drive ecosystem processes and services (Diaz and Cabido 2001; Lavorel and Garnier 2002; Hudson et al. 2011). In fact, it has even been suggested that functional traits should be the key unit of scientific inquiry for community assembly processes—especially in regard to environmental change (McGill et al. 2006). Therefore, knowledge of the ways in which changes in the environment may impact functional trait composition, diversity, and associated functional assembly processes is of vital importance not only to ecologists but to the human society as a whole (Chapin et al. 1996; Costanza et al. 1998; Balmford et al. 2002).

4.19.4 Functional Response Traits and Functional Assembly within Communities

A basic tenet of community assembly theory is that 'filters,' both abiotic and biotic, select species from the regional species pool to assemble a local community most suited to the prevailing conditions, in a process known as ecological sorting (Weiher and Keddy 1995; Diaz et al. 1998; Ackerly 2003). These filters then continue to act on the community, thereby altering its composition as the parameters of the filters themselves change (Diaz et al. 1998; Shachak and Boeken 2010).

Traditionally, community assembly via environmental filters has been viewed at the species level, where species are individually sorted from the regional pool (Shipley et al. 2006). However, more recently, it has been recognized that species can be grouped according to their functional trait associations, where species within each group share a number of nonrandomly associated functional traits (Diaz et al. 1998; Ackerly 2003; Fynn et al. 2011). When these traits are used to measure the community response to environmental change, any species sharing such traits can be grouped into 'functional response types' (Lavorel and Garnier 2002; Suding et al. 2008). It is these functional traits that may be acted upon by community assembly processes (Lavorel and Garnier 2002; Fukami et al. 2005; Holdaway and Sparrow 2006; Webb et al. 2010), with environmental filters determining the optimal trait values, abundances, and composition at any one site (Messier et al. 2010; Fynn et al. 2011).

If this model is accurate, and community assembly for trait-based functional groups is deterministic (e.g., controlled by environmental filters (Fukami et al. 2005)), then the impacts of environmental change on the functional traits of assemblages will be unavoidable. Assembly still technically occurs at the species level; however, species with similar suites of traits respond to selection pressures in a similar way—resulting in selection by change drivers for functional response groups as a whole (Lavorel and Garnier 2002; Webb et al. 2010). The widely recorded link between species traits and environmental conditions bears testament to this fact (Diaz et al. 1998; Ackerly 2003; McGill et al. 2006; Laliberté et al. 2010), and there are a growing number of examples of environmental change drivers affecting optimal values of traits that are likely to carry implications for ecosystem functioning.

4.19.5 Environmental Changes Select for Functionally Important Traits: Examples

Suding et al. (2008) proposed that, as a result of environmental change, directional changes in biotic and abiotic controls of ecosystems would occur, translating into subsequent directional changes in trait distributions and composition within plant communities. Already well documented are the general patterns of changes in response traits that we might expect to see in regard to specific drivers. However, what is not well documented is the subsequent implications of such response patterns for ecosystem functioning—both in terms of magnitude and persistence. In the following examples, we present instances of single environmental change drivers selecting for specific values of potentially functionally important traits, with their probable effect on ecosystem processes.

4.19.5.1 Plant Height Affected by Climate and Land-Use Change

Plant height is generally associated with growth strategy type, with tall, fast growing, light competitive species being at the 'acquisition' end of the acquisition–conservation trade-off—and thus being more palatable (and therefore susceptible) to grazing herbivores. As a result, plant height may be a good indicator of ecosystem biomass turnover, as more palatable species will experience higher turnover rates.

Many functional traits are found to be affected by changes in temperature (Gratani et al. 2000; Pakeman et al. 2008a; Hudson et al. 2011; Yang et al. 2011), and it could be expected that, because arctic and alpine areas are particularly sensitive to temperature increases (Wookey et al. 2009; Yang et al. 2011), selection will be strongest on traits in these regions. Accordingly, an increase in average plant height was found for four tundra species subjected to experimental warming treatments, although there was significant variation within species plots (Hudson et al. 2011). An important point of interest was that these changes were not transitory; plant trait responses were sustained for almost two decades, contrasting starkly with the authors' hypothesis that long-term sustained responses would require a simultaneous increase in nutrient levels. The findings of Hudson et al. (2011) are consistent with the overall general expectation that warming would on average increase plant height (Wookey et al. 2009) and hence affect both biomass turnover rates and nutrient cycling.

In addition to climate effects, the proportion of land transformed across the globe since 1945 is thought to range from between 40 and 50% (Vandewalle et al. 2010). In a study looking at the impact of land-use change on plant functional responses across Europe, the overall trend across the 11 study sites was to see a decrease in plant height with increased land disturbance (Garnier et al. 2007). Interestingly, regardless of the type of land disturbance to which communities were subjected (e.g., grazing, plowing, etc.), there were general commonalities in responses of traits—suggesting that disturbance intensity, not type, was the most important determinant of land-use change effects (Garnier et al. 2007).

The same pattern of association between plant height and intensity of habitat modification was also demonstrated by Diaz et al. (2007), where shorter plants were selected in more intensely grazed areas. The authors looked at grazed systems across a variety of climates, and in general this same pattern was repeated, suggesting that these effects may be widespread. However, Diaz et al. (2007) found no uniform relationships between categories of species such as forbs, graminoids, and woody vegetation, further lending support to the utility of functional-trait classifications, rather than a priori functional grouping of species.

4.19.5.2 Leaf Traits Respond to Climate

Leaf dry mass per unit area (LMA) is a measure of thickness and/or density of leaf tissue, which allows an approximation of leaf dry matter investment per unit of light intercepting area of leaf deployed (Wright et al. 2004). Leaf mass scales up to the ecosystem process of leaf–litter decomposition, with leaves that have a higher LMA (and hence, more dry matter per leaf), decomposing more slowly (Garnier et al. 2007). A decrease in LMA was found with artificial warming for an alpine plant species *Kobresia pygmaea* (Yang et al. 2011) and for a variety of plant species at 11 sites across Europe (Garnier et al. 2007). The fact that identical relationships between LMA and temperature were found over such a diverse environmental range clearly points to this relationship being a generality—with the expectation being that increased warming should accelerate rates of decomposition. This will have significant implications for biomass turnover and nutrient cycling.

Net leaf photosynthetic assimilation rate per unit mass at saturating light levels (Amass) is a response trait that can be used to approximate net primary production (NPP) at the ecosystem level (Wright et al. 2004), and as such, provides a valuable response-effect linkage. A positive relationship between photosynthetic capacity and temperature seems to be a general relationship across very different environments, with increased photosynthetic capacity of leaves being observed in warmer areas of the Mediterranean for the plant species *Quercus ilex*, and for experimentally warmed plots of the tundra species *K. pygmaea* (Gratani et al. 2000; Yang et al. 2011). An extension of these results would suggest that there may be an increase in NPP globally in those regions where warming occurs.

Changes in leaf nitrogen and phosphorus are good approximations of the nutrient acquisition–conservation trade-off, with reduced concentrations of these chemicals relating to a slower and more conservative growth strategy. Leaf carbon concentration was found to decrease with warming for two tundra plant species (though again results were site specific) (Hudson et al. 2011). Similar effects of warming on leaf chemistry were found for *K. pygmaea*, with decreases in leaf carbon, nitrogen, and phosphorus concentrations and a reduction in leaf C:N ratio, which is thought to be due to increased efficiency of N use (Yang et al. 2011). Therefore, warming is seen to favor conservative (N efficient) growth forms. However, this could also be related to increased temperatures driving accelerated growth, and thus nutrient levels in the soil may become depleted, with plants having no choice but to adopt more conservative strategies.

In addition to the above changes in leaf characteristics within species, there can also be changes in community-wide mean trait values. In particular, warmer temperatures can facilitate plant invasions (including by noxious weeds), and invaders may have a different set of traits to the native species in the invaded community (Sandel and Dangremond 2012). For example, a study in California found that exotic species were taller, with longer and wider leaves and higher specific leaf area and leaf nitrogen content than their native counterparts (Sandel and Dangremond 2012). These traits tended to be favored by warmer temperatures, and it was found that warmer areas had higher proportions of exotic species.

4.19.5.3 Body Size Distribution Altered by Land-Use Intensity

Body size of animals is correlated with a large number of life–history parameters, such as metabolic and reproductive rate, dispersal ability, longevity, etc. (Gaston and Blackburn 1995; Cohen et al. 2003; De Roos et al. 2003; Woodward et al. 2005; Reuman et al. 2009). As such, body size has been shown to be an important parameter in the structuring of food webs (Woodward et al. 2005; Otto et al. 2007; Laliberté and Tylianakis 2010) and in the contribution of a species to ecosystem functioning (Larsen et al. 2005; Hoehn et al. 2008). Thus, like the plant traits above, it can be viewed as both a response and an effect trait (see below).

Land-use intensification at local and landscape scales has been shown to select for smaller-bodied species. For example, land-use intensification can reduce the mean body size of bees and wasps (Hoehn et al. 2008; Laliberté and Tylianakis 2010), and larger-bodied bees and dung beetles have also been shown to go locally extinct more rapidly with a loss of natural habitat from the landscape (Larsen et al. 2005). This nonrandom loss of larger-bodied animals has important functional consequences, as body size can be positively correlated with the ability to perform functions such as dung burial and pollination (Larsen et al. 2005; Hoehn et al. 2008).

4.19.5.4 Loss of Functional Groups

The results presented above clearly show that environmental changes can change the parameters of environmental filters, and subsequently change the trait value optima for a number of traits. Shifts in trait optima are also altering community composition, and this presents a new and even more concerning possibility—that, rather than shifts in the magnitude of ecosystem functioning (via selection for new optimal trait values), we may see elimination of entire functional groups, whose spectrum of trait values do not fall inside the newly defined selection criteria of the changed environmental filters (Vinebrooke et al. 2004). In other words, entire functional groups are lost if environmental conditions exceed their tolerance (Hampe and Petit 2005). Such elimination of functional groups could have drastic effects on ecosystem functioning, as single functional groups may drive ecosystem processes (e.g., legumes fixing nitrogen).

The studies by Hoehn et al. (2008) and Larsen et al. (2005), discussed above, showed that land use can drive the loss of pollinator functional effect groups, and that this reduction can significantly impact pollination success. Similarly, climate can drive the local elimination of functional groups. For example, shading due to increased plant height in the Arctic is eliminating lichens and mosses, either completely or reducing them to abundances whereupon they become functionally extinct (Wookey et al. 2009). If the response traits of a species were completely independent of its effect traits, predicting the impacts of environmental changes on ecosystem functioning would be considerably more difficult. However, the above examples demonstrate that the traits of a species may determine both how it responds to environmental change and how it contributes to ecosystem functioning.

4.19.6 Linking Response with Effect Traits

Species can be classified into functional groups within two broad categories: (1) functional response types—a group of species that responds to the abiotic and biotic environment in a similar way; or (2) functional effect types—a group of species that similarly affect ecosystem processes and drive positive effects of diversity on functioning (Diaz and Cabido 2001; Lavorel and Garnier 2002; Suding et al. 2008; Laliberté et al. 2010). Lavorel and Garnier (2002) recognized the need to identify linkages between response and effect traits, and subsequently proposed a framework with which to do so. The main conclusion of their proposed framework was that traits involved in fundamental trade-offs (such as in nutrient acquisition and conservation) would scale up to biogeochemical cycling at the ecosystem level. Such traits could then be used to predict impacts on ecosystem processes, for example those traits that act as both response and effect traits (Garnier et al. 2007; Minden and Kleyer 2011). This idea was further developed by Suding et al. (2008), with the plant trade-offs in question being based on the leaf economics spectrum (Wright et al. 2004; Shipley et al. 2006).

In essence, due to the mechanism of ecological sorting (Ackerly 2003), it could be hypothesized that functional reassembly will occur in all communities subject to the effects of global environmental change (Shachak and Boeken 2010). Such changes in functional composition and diversity present a worrying unknown, as rates and magnitudes of ecosystem processes are consistently found to be closely associated with these two measures (Diaz and Cabido 2001).

Therefore, linking the responses of such assemblages, both in their initial assembly and reassembly of already established communities, to the effects of environmental changes on ecosystem function has become a paramount issue for the earth science community. Most importantly though, the response–effect trait framework provides a powerful way to determine how the ecological and evolutionary selection pressures of multiple change drivers (and their effects on biotic and abiotic filters) could impact ecosystem functioning (Diaz et al. 1998; Shachak and Boeken 2010). That is, individual drivers of environmental change may select for novel trait distributions within a functional group (Webb et al. 2010) or select certain functional groups nonrandomly over others, thereby altering functional composition and potentially eliminating (or adding) entire functional groups (Diaz and Cabido 2001; Vinebrooke et al. 2004). The combined effect of multiple drivers, and whether their effects will be additive, synergistic or antagonistic, will thus be determined by the extent to which their selective effects on species traits are positively or negatively correlated.

4.19.7 Response Diversity and the Possibility of Co-Tolerance

Response diversity refers to the number of different functional response types represented within one functional effect type—that is, how functionally similar species differentially respond to the same environmental changes (Elmqvist et al. 2003; Laliberté et al. 2010). In light of the previous discussion, this 'response diversity' will play a critical role in determining the continued maintenance of ecosystem functioning in changing environments. This is because functional effect types with high response diversity are more likely to have at least one response type that falls within the trait optima of the new selection regime.

For many plant species, extended growing seasons translate into selection for plant traits that allow an increase in productivity (Piao et al. 2007), especially for high-latitude species (Keyser et al. 2000). However, a recent study manipulating growing season length of three alpine species (by controlling timing of snow melt) found no such effects. The lack of response was attributed to the fact that all three species were 'periodic' species and thus genetically constrained in terms of their growth period (Baptist et al. 2010). This highlights an important aspect of response diversity (and in this case the lack thereof). All three plant species contributed to NPP (which can be approximated by above-ground biomass) but show the same 'fixed' response to climate; they are unable to increase ecosystem productivity even when environmental conditions will allow such an increase. Thus, low response diversity can be an important limiting factor in ecosystem functioning.

It therefore becomes important to know whether specific environmental changes cause a reduction in response diversity, as this will affect resilience to further perturbations. The above examples of drivers selecting for certain trait optima suggest that extinctions will in general not be random (e.g., Larsen et al. 2005). Rather, species with similar traits will be lost (see 'Loss of functional groups' section above), and this could be expected to drive a loss of response diversity when whole response types go extinct. To test this hypothesis, Laliberte et al. (2010) conducted a meta-analysis of 18 data sets of land-use intensification studies, and found that 9 of the data sets displayed a negative relationship between land-use intensity and response diversity. This statistically significant result demonstrated that response diversity is depleted as a result of increasing intensification land-use practices. Moreover, a loss of response diversity driven by one change driver (e.g., land use) could reduce the ability of a system to cope with other additional drivers (Elmqvist et al. 2003). The extent to which this occurs will depend ultimately on whether or not the optima selected by different drivers are correlated. In other words, do both drivers select for the same response traits, such that one driver generates communities that are able to withstand another driver, or do the drivers pull the response traits of a community in different directions (**Figure 2**)?

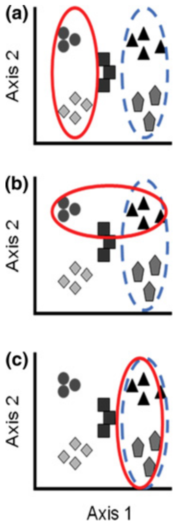

Figure 2 Ordination plots of hypothetical multivariate response traits under the effect of two environmental drivers. Points (species) that are close together have similar combinations of (correlated) traits, and those that are most similar form a functional group (those points with the same shape). Two drivers (dashed and solid ovals) each select for certain functional traits, with those species outside of the selection area being driven locally extinct. Depending on the degree of correlation in the traits selected by each driver, they may exhibit (a) no co-tolerance, (b) partial co-tolerance, or (c) complete co-tolerance.

Vinebrooke et al. (2004) suggested that the sensitivity of a species to different stressors could be positively or negatively correlated. When generalized across a community, a positive correlation would result in species persisting that are more tolerant of subsequent environmental stressors, following elimination of a subset of vulnerable species by the initial stressor. Conversely, negative correlation would result in more susceptible species being left to be acted upon by subsequent stressors. If such co-tolerance occurs among functional groups in the same way as species, then the direction of co-tolerance will determine the extent of functional-diversity loss under a suite of environmental changes (Figure 2). Specifically, we would expect to see less of a decrease in response diversity where there was positive co-tolerance, and an accelerated reduction in response diversity where there is negative co-tolerance.

Co-tolerance of species and functional groups to environmental changes thus provides a framework for understanding how multiple drivers may alter ecosystem functioning. Indeed, to fully understand the cumulative effects of environmental change on ecosystem functioning, we must better understand the potential non-additive effects on ecosystems of multiple change drivers acting simultaneously.

4.19.8 Evidence of Interactions among Drivers

Above, we have outlined how environmental change drivers may select for optimal values of key functional traits. Although in some cases two different drivers may select for the same trait optimum (functional trait co-tolerance), any divergence in optima could produce non-additive effects on ecosystem functioning. The idea that multiple drivers of change may have non-additive effects on species and ecosystems is gaining momentum in the literature, though many studies still focus on only one driver, and where multiple drivers are addressed, interaction effects are often not considered (Vinebrooke et al. 2004; Didham et al. 2007; Tylianakis et al. 2008a). The independence of different drivers is often assumed implicitly, when the effects of one driver are presented without reporting the context of any other drivers. Nevertheless, numerous studies have uncovered interactive effects of multiple drivers on endangered species (Didham et al. 2007), biodiversity (Brook et al. 2008), and species interactions (Tylianakis et al. 2008a). In fact, even a meta-analysis that attempted to argue for the rarity of synergistic effects (among broadly defined ‘stressors’) revealed that 77% of studies showed non-additivity in the effects of multiple stressors, of which 35% were synergies (effects greater than the sum of each stressor in isolation) and the remainder were antagonistic (sub-additive) effects (Darling and Cote 2008).

Didham et al. (2007) described two pathways through which environmental change drivers may have interactive effects on species. The first of these was termed an ‘interaction chain effect,’ whereby one driver affected the extent or level of another driver, but the per unit effect of each driver remained constant. For example, elevated CO_2 (one driver) drives an increase of night-time minimum temperatures (Steeneveld et al. 2011, (another driver)), though CO_2 does not necessarily alter the per unit (e.g., per degree of change) effect of warming. In contrast, the second pathway, which was called an ‘interaction modification effect’ (Didham et al. 2007), requires one driver to affect the per unit effect of another driver. For example, nutrient addition (e.g., through land-use change or N deposition) can promote lower root:shoot ratios in grassland plants, making them more susceptible to a given level of drought (Givnish 1994).

Although these concepts were applied to species, analogous processes could occur in the selection of functionally-important traits. Interaction chain effects could operate in a similar way, and modification effects could occur through context dependency in the effect of drivers on trait optima (Pakeman et al. 2008b). For example, the earlier example of warming selecting for taller tundra plant species could easily be exacerbated by nitrogen or phosphorous deposition reducing nutrient limitation of taller species. The earlier examples of context dependency in the biodiversity-ecosystem functioning relationship provide another possibility for interaction modification effects. In this case, the per unit indirect (biodiversity-mediated) effect of one driver would depend on the extent of another driver (e.g., trait diversity becomes more important for productivity under nutrient enrichment, Laliberté and Tylianakis 2012).

Relatively few studies have examined the effects of multiple drivers on biodiversity and/or ecosystem functioning, compared with the number of studies measuring effects of single drivers, or of multiple drivers affecting, for example, the physiology of a single species. However, a lack of information about interactions was cited by the Millennium Ecosystem Assessment (2005, p. 101) as a major limitation to scenarios for the future of ecosystem services. Furthermore, when Sala et al. (2000) explicitly addressed interactions among drivers, they found that the inclusion of interaction effects severely altered biodiversity outcomes. Given the myriad potential interaction chain and modification effects among all of the drivers of environmental change, and the likelihood of negative co-tolerance as drivers select for different trait optima and exert differential effects on species physiology, we expect that an increasing number of studies will demonstrate non-additivity in the effects of multiple change drivers on biodiversity and ecosystem functioning.

For example, a recent review by Schweiger et al. (2010) concluded that changes in local and regional climate and invasive species would generate novel communities, with potential effects on ecosystem functioning. Generalist species are likely to be favored by both of these drivers, invaders may preferentially interact with other invaders to the exclusion of native species (Aizen et al. 2008), and changing climatic conditions might promote further invasions (an interaction chain effect sensu Didham et al. 2007; Schweiger et al. 2010). Thus, the interactive effect of these drivers may alter biodiversity and select for traits such as generality.

Selection of functional traits may be a key mechanism through which environmental change drivers may interact; however, any of the pathways through which changes can affect ecosystem functioning (Figure 1) are potentially subject to non-additivity when multiple drivers occur in combination. Yet, despite the known importance of this non-additivity for extinction of species, disruption of interactions, and the future of biodiversity (Sala et al. 2000; Didham et al. 2007; Brook et al. 2008; Tylianakis et al. 2008a; Schweiger et al. 2010), most national and international policy mechanisms are aimed at mitigating a single driver of environmental change (e.g., the Kyoto protocol, agri-environment schemes, and at least 16 international legal instruments have programs or activities that are relevant to invasive species). Although the reasons for this disconnect are likely to be pragmatic, rather than philosophical, mitigation of the cumulative risks to ecosystem functioning will ultimately require communication and coordinated action among these policy mechanisms.

4.19.9 Conclusions and Implications

The Earth's ecosystems are at the verge of passing into what is described by Suding et al. (2008), as 'no-analogue' functional communities. Anthropogenic drivers of environmental change are an ecological pressure unique to our time. The uniqueness of these drivers translates into unique changes in functional trait composition, diversity and abundance; as these drivers act as ecological filters and cause functional reassembly of communities. If we are ever to predict such changes, traits with both response and effect linkages must be further identified and more widely used in studies looking at ecosystem responses to environmental change. The generalized frameworks of Lavorel and Garnier (2002) and Suding et al. (2008) will make this undertaking much more accessible.

Finally, the impacts of multiple drivers on communities, particularly interaction effects, need to be more widely recognized, reported, and incorporated into policy. While assessing interactions between drivers may be viewed as requiring more involved and complicated experimental designs, this may not be the case—many published studies already have the relevant data, and even reporting explicitly the environmental context of experiments could provide useful information. In terms of mitigating effects of environmental change, our greatest challenge will be to understand how changes to biodiversity, community structure, and trait optima brought about by one driver may provide greater or lesser resilience against another. In essence, the responses of biotic communities to a suite of environmental change drivers, and their link to myriad ecosystem services, will ultimately determine our survival.

Glossary

Alternative states Ecosystems with similar climate and soils, yet different species, interactions, and processes.

American Southwest The arid region (<25 cm rainfall per year) of the United States that includes the three hot deserts (Chihuahuan, Sonoran, Mojave).

Desertification The broad-scale shift from productive, native perennial grasslands or savannas to dominance by native or non-native annuals, unpalatable herbaceous and woody plants, and/or increasing amounts of bare ground.

Grassland Ecosystem where the vegetation is dominated by grasses and other herbaceous (nonwoody) plants, such as forbs.

Invasive species native or non-native species that have increased dramatically in an ecosystem as a result of changes in climate and/or human activities.

Novel ecosystem Ecosystem comprised of different species, interactions, and processes not possible under current conditions and not reflected in past systems.

Savanna Ecosystem characterized by a mixture of grasses and woody plants (shrubs, trees) where the woody plants are sufficiently small or widely spaced so that the canopy is not closed. The open canopy allows sufficient light to reach the ground to support the herbaceous layer of grasses.

Shrubland Ecosystem dominated by short (typically <8 m tall) woody plants often with many stems.

Soil inorganic carbon (carbonate) Compounds in the soil containing carbon that are not created by living organisms, but are derived from minerals in the Earth. The most common form of carbonate in dryland soils is calcium carbonate ($CaCO_3$) that forms when minerals are leached by rainwater from upper layers of the soil and accumulate in lower layers. Hardened deposits of calcium carbonate are called caliche.

Soil organic carbon Compounds in the soil containing carbon material derived from decaying vegetation, bacterial growth, and metabolic activities of living organisms or chemicals.

4.20.1 Introduction

Arid and semi-arid grasslands and shrublands (i.e., dryland ecosystems) comprise nearly 40% of the Earth's land surface and influence the livelihood and well-being of one-fifth of the world's human population (Reynolds and Stafford Smith 2002). Plants and animals associated with these ecosystems often exist near their physiological limits such that slight increases in temperature, decreases in precipitation amount, or shifts in seasonality can have disproportionately large effects relative to those in other ecosystems. Furthermore, changes in the abundance and cover of vegetation in these drylands can have profound effects on soil erosion and exchanges of energy and water between the land surface and the atmosphere; these bottom-up effects can intensify stresses associated with climate and act to initiate self-reinforcing changes in vegetation (feedbacks). As a result, arid and semi-arid grasslands are highly susceptible to desertification – the broad-scale shift from productive, native perennial grasslands or savannas to dominance by native or non-native annuals, unpalatable herbaceous and woody plants, and/or increasing amounts of bare ground. As reviewed in this chapter, these ecosystem modifications have significant consequences for myriad ecosystem provisioning, regulating, supporting, and cultural services via their influence on carbon storage, biodiversity and forage production, spread of invasive non-native species, the partitioning of hydrological budgets, wind and water erosion, and land surface influences on atmospheric chemistry and weather. The social aspects of the vulnerability of these ecological systems to change are discussed in Ojima et al. (in press, see Chapter 4.17).

Desertification is the result of cumulative threats that interact in time and space (Figure 1). Each threat operates on ecosystems at local scales that can propagate to influence broad-scale dynamics with consequences for ecosystem services. Carbon dioxide enrichment (CO_2), nitrogen (N) deposition, and climate are broad-scale; regional threats that constrain or amplify effects of finer-scale threats and responses to weather events (Figure 2). These local threats include the following:

1. Extreme weather events (drought, flood, wind storms)
2. Land use (human preemption of landscapes, including suburbanization, dryland farming and fragmentation)
3. Land management (primarily livestock grazing, noxious plant management)
4. Establishment and spread of non-native species

Both the broad-scale drivers and local threats are changing through time such that the future of drylands is highly uncertain. For example, surface air temperatures are increasing in some regions for at least part of the season, and atmospheric CO_2 levels are increasing globally, yet global climate models disagree on how precipitation will change in magnitude, seasonality, and even direction (increase, decrease) in drylands. Nitrogen deposition may increase or decrease in the future depending on the source of nitrogen inputs into the atmosphere and the geographic location (e.g., proximity to cities). Local threats are also changing, and in many cases these changes are nonlinear through time and space, and depend on interactions among broad-scale drivers, land surface and ecological characteristics, policy decisions, and local management practices.

In the future, interactions among broad-scale drivers and localized threats are expected to increase the likelihood of creating alternative ecosystem states (e.g., grass states shrub states; perennial plant states annual plant states, etc.). When coupled with changes in atmospheric chemistry, such as CO_2 concentrations and N-loading, these threats are likely to create 'novel ecosystems' (ecosystems comprised of different species, interactions, and processes not possible under current conditions and not reflected in past systems). These alternate states will have different consequences for ecosystem services. Our challenge in this chapter is to determine the vulnerability of different ecosystem services to changes in drivers and ecosystem states, with a focus on the American Southwest. In addressing this challenge, we first sought to (1) briefly describe key ecosystem services in drylands, (2) identify and articulate the consequences of desertification to each ecosystem service (historical to current-day perspective), and (3) explore the vulnerability of each ecosystem service to future state-change effects if existing threats intensify and new threats emerge. We then synthesize this information to determine the threats expected to have the greatest future impact (positive–negative) on desertification and ecosystem services for alternative states, and provide potential actions for mitigation. We conclude with recommendations for land managers, policy makers, and other stakeholders.

4.20.2 Effects of Desertification on Ecosystem Services

4.20.2.1 Regulating Services

4.20.2.1.1 Energy Exchange and Land–Atmosphere Interactions

Understanding how various drivers of environmental change interact to affect the Earth's energy balance is one key to understanding the future state of the Earth system and how humans will need to adapt in order to live more sustainable. Energy balance is the difference between the total incoming and total outgoing energy within the Earth's atmosphere, because the Earth receives almost all of its radiation from the sun – an energy balance of 0 means that all incoming radiation from the sun equals all outgoing radiation. If energy balance increases above 0, the Earth's atmosphere will warm, and it will cool if the energy balance falls below 0. This balance is closely met on the annual average, but intraannual values are not. Many factors control how much energy from the sun arrives at the Earth's surface each year (e.g., sun spots, orbital patterns of the Earth, clouds), how the radiation reaching the surface is reflected or absorbed (e.g., soil color, snow cover, vegetation type and density, soil moisture content), and the extent to which it is trapped or re-emitted back into space by greenhouse gases. The influence of these factors (known as radiative forcing potential) can be assessed for their respective capacity to alter energy balance (Baldochi, in press see Chapter 4.10).

Properties and processes controlling radiative forcing potential in dryland ecosystems have received increased scientific attention for at least three reasons: (1) Arid landscapes with low vegetative cover and high bare ground cover are typically a net sink for radiation and a net source of heat energy to the atmosphere; (2) the land surface area covered by arid landscapes

Adapted from Millennium Ecosystem Assessment (2005)

Figure 1 Historically, the predominant state change in arid and semi-arid regions globally was associated with desertification, the broad-scale conversion of perennial grasslands, shrub-steppe, and savannas to systems dominated by xerophytic, unpalatable shrubs on degraded soils or to annuals on degraded soils. Desertification results from cumulative, interacting threats that may intensify with regional climatology. Degraded systems, in turn, would be vulnerable to future threats that may lead to alternative states, including novel ecosystems. Future threats would also influence the rate and extent to which management can repair or restore degraded systems to prior and more desirable states. As state changes occur, ecosystem services (ES) would be impacted. (Photos from Jornada USDA-LTER photo library.)

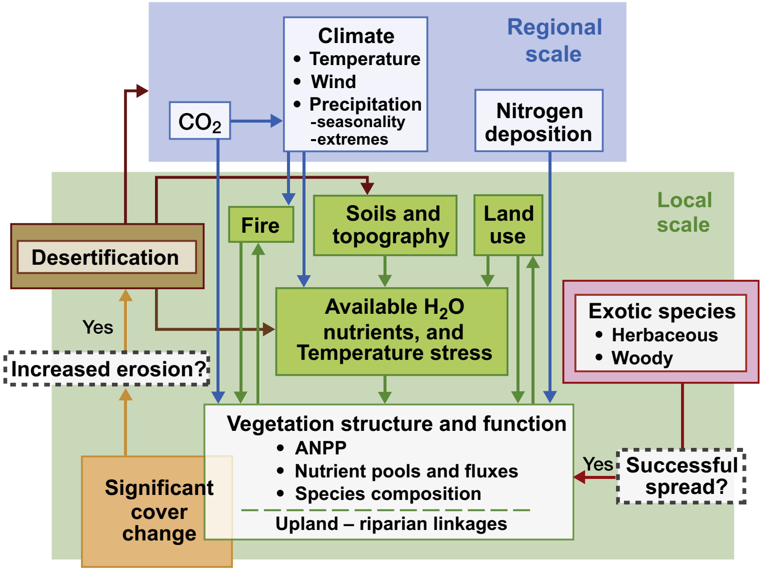

Figure 2 Organizational framework for interpreting climate, land cover effects, and their feedbacks on desertification of dryland ecosystems at local and regional scales (Ryan et al. 2008).

is increasing globally with desertification (Archer 2010); and (3) ecosystem states accompanying desertification (Figure 1) positively reinforce and sustain altered microclimatic conditions of desertified states, thereby making it difficult to restore former ecological states such as grasslands. Additionally, many arid regions such as the American Southwest could become drier and experience more extreme climatic events, such as prolonged droughts and flooding events (Seager et al. 2007). Impacts of increasing human populations, altered land use, and introduced species are expected to interact with climate to influence land–atmosphere interactions with feedbacks to climate and sustainability of drylands in the future. Understanding the sustained and cumulative impacts, and potential tipping points associated with such change remains an urgent challenge to researchers, policy makers, and land managers.

Consequences of Desertification for Energy Exchange and Land–Atmosphere Interactions

Transitions between grasslands and shrublands can alter the energy balance of arid landscapes over relatively large areas (Figure 3; Beltran-Przekurat et al. 2008; Nair et al. 2007). Due to the typically lower vegetation cover and greater reflectivity of soil compared to plants, sparsely vegetated shrublands reflect a larger amount of incoming radiation than grasslands with a lower albedo (Kurc and Small, 2004). When water is lost from soils (evaporation) and plants (transpiration), cooling can occur because energy is dissipated as water transitions from a liquid to a gaseous state (latent heat exchange). This loss of energy to the atmosphere depends on a number of factors, including soil physical properties and moisture content, leaf area within the plant canopy, and the capacity of air masses within the canopy to mix with air above it. The latter is controlled by factors such as wind speed, roughness, and vertical structure of the plant canopy.

Many differences in the partitioning of surface energy balance between grasslands and shrublands depend on the differences in the biology between grasses and shrubs, such as their physiology and timing of growth (C_4 grasses in summer, C_3 shrubs in spring and fall), their root distributions (shallow-rooted grasses can be more coupled to precipitation compared with deep-rooted shrubs that access stored water), and canopy structure (dense bunchgrasses, open shrub canopies). Thus, impacts of shrub encroachment on energy balance can differ among desert systems (Eldridge et al. 2011), and the dynamics at one site do not necessarily translate to others. The need for a more robust understanding of the consequences of land cover change on ecosystem energy balance is a key motivation for desertification research.

Land cover changes that modify surface energy balance affect a gamut of local to global ecosystem goods and services. On a local scale, the increased heat storage associated with depleted soil moisture and altered land surface properties in shrublands can promote water stress and limit photosynthesis in grasses, thereby reducing their productivity, biomass (see Section 4.20.2.3.1), and forage production (see Section 4.20.2.2.2), while creating conditions conducive to the establishment of unpalatable, xerophytic shrubs. In shrublands, soil moisture is likely to be reduced at greater depths due to the deeper penetration of shrub roots compared to grasses (Gibbens and Lenz 2001). Because of the large expanses of shrublands, these local effects manifest to impact landscape to regional scale processes, including sensible and latent heat exchange, heat storage, and surface water balance. These changes can influence and potentially alter regional climate by depleting atmospheric moisture, decreasing cloud cover, and increasing drought cycles as well as modifying radiative forcing potential.

Threats to Future Trends in Energy Exchange and Land–Atmosphere Interactions

Changes in surface energy balance, accompanying and underpinning future stresses of desertification have the

Carbon sequestration by plant–soil–microbial processes occurs both above and below ground (Archer 2010).

potential to affect a range of stakeholders over a sustained period of time, due to the broad spatial extent of these changes and the reinforcing feedbacks associated with altered ecosystem states. Warmer, drier conditions accompanying grassland to shrubland conversion would reinforce the displacement of relatively palatable mesophytic grasses by unpalatable xerophytic shrubs with reductions in overall plant productivity, livestock carrying capacity, and vegetation cover (Fredrickson et al. 1998; Barger et al. 2011; Peters et al. 2011). Associated with these changes would be the opportunity for invasion from exotic species, and altered human well-being and health through the increased capacity for dust storms – especially during periods of prolonged drought forecast for the region (see Section 4.20.2.3.2). At a larger scale, reductions in atmospheric uptake potential or enhanced radiative forcing potential of shrublands (see Section 4.20.2.1.2) may result in increased reliance on ecosystems in other bioclimatic zones to uptake carbon dioxide.

4.20.2.1.2 Carbon Storage (Organic, Inorganic)

The amount of carbon released into the atmosphere each year via fossil fuel combustion is estimated at 5.5 Pg (IPCC 2007). While this is a small component of the annual global carbon budget, the cumulative effects on the atmosphere can be quite important. Since 1850, the atmospheric concentration of carbon dioxide (CO_2) has increased from 275 ppm to more than 390 ppm. This increase in atmospheric CO_2 and other greenhouse gases (GHG) is a major contributor to documented increases in average global surface temperature (1 °C since 1900), and is hypothesized to have major impacts on regional climate (Seager et al. 2007). Substantial resources have been devoted to developing GHG mitigation technologies to reduce emissions; however, carbon sequestration in natural and managed ecosystems remains the only economically viable means of removing carbon from the atmosphere (Pacala and Socolow 2004; but see Section 4.20.4). Vegetation, via photosynthesis, takes up carbon in the form of CO_2 from the atmosphere, converts this greenhouse gas into complex organic structures, and then transfers it into the soil with the death and decomposition of plant leaves, roots, and stems. This organic plant debris is then converted to other stable carbon compounds via microbial assisted processes. The regulation of climate via CO_2 sequestration by plant–soil–microbial processes (Figure 3) is an important ecosystem service threatened by desertification where both the levels of stored soil carbon and the capacity to increase its storage are diminished. In addition, many drylands are heavily grazed and the carbon removed by grazers is exported off-site. Here we discuss both organic and inorganic soil carbon that are important in arid and semi-arid regions of the world, including the American Southwest.

The amount of organic (readily exchangeable) carbon stored in soils and vegetation globally exceeds 2000 Pg (1 Petagram = 10^{15} g = MMT). Soils contain 1400–1600 Pg of organic carbon, and vegetation is estimated to contain 500–600 Pg (IPCC 2007). Of this total amount, about 120 Pg moves back and forth between the soil–vegetation complex and the atmosphere on an annual basis (flux). By comparison, oceans with the largest pool contain about 38 000 Pg and the atmosphere contains about 750 Pg. Dryland ecosystems contain approximately 363 Pg of carbon (Post et al. 1982). This pool of carbon is equal to the amount stored in croplands and wetlands combined (370 Pg), and is only slightly less than pools associated with forest ecosystems (470 Pg). Although drylands represent a significant portion of the global soil carbon pool, managing them for an increase in storage is a challenge. For any specific unit of land, high spatial variability and year-to-year changes in factors controlling carbon flux (precipitation, temperature) make management highly uncertain, and prediction and measurement difficult and expensive. At larger scales, the same problems are confounded by the vast areas involved, and make credible accounting systems and the policies and programs they support difficult to construct.

Inorganic carbon, stored as calcium carbonate ($CaCO_3$), is also a significant portion of the global carbon budget (**Figure** 4(a)). The global amount exceeds 940 Pg, making it the third largest carbon pool (Eswaran et al., 2000). Inorganic carbon exists in arid and semi-arid soils as light colored subsoil horizons that develop when small calcite crystals (2–10 μm) are precipitated in the pore spaces between sand and silt particles. The longer a dryland soil has been exposed to weathering at the Earth's surface, the greater the amount of inorganic carbon in its subsoil.

The role that inorganic carbon plays in the global carbon cycle, especially with respect to carbon storage, is more complicated than organic carbon because it depends on the

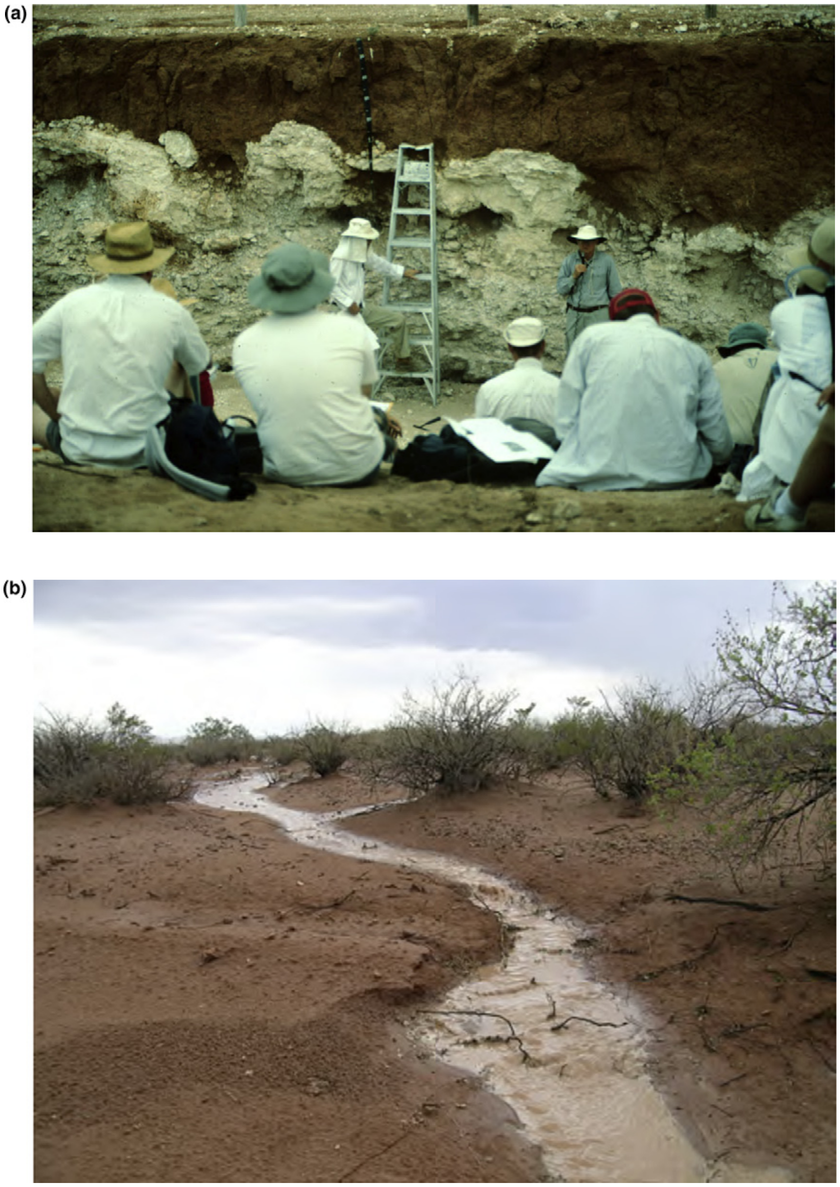

Figure 4 (a) Inorganic carbon (shown as light colored layer at variable depths), stored as calcium carbonate ($CaCO_3$), is a significant portion of the global carbon budget. Figure 4 (*Continued*).

calcium biogeochemical cycle. A lexicon to explain how and when different types of inorganic carbon are formed is still developing. For example, 'Soil Carbonate' is the broadest category and refers to the total amount of carbonate in soil. This category is subdivided into 'Lithogenic Carbonate' (carbonate particles physically derived from limestone or similar bedrock) and 'Pedogenic Carbonate' (carbonate crystals precipitated from solutions in the soil). If the source of calcium in pedogenic carbonates is from preexisting carbonate minerals, such as particles of limestone, there is no gain in carbon storage with its formation. This is because the amount of carbon dioxide (CO_2) consumed to form carbonic acid, which reacts with and dissolves the limestone particles, is the same amount of CO_2 released upon the formation of pedogenic carbonate (Monger and Martinez-Rios 2000). However, pedogenic carbonates whose calcium is derived from silicate minerals is a potentially strong sink for atmospheric CO_2 because the carbon in the $CaCO_3$ precipitate is derived from CO_2 respired from roots and microbes; this CO_2 could otherwise leave the soil and return to the atmosphere.

Consequences of Desertification for Carbon Storage

Drylands with low plant production (see Section 4.20.2.3.1) and low organic soil carbon are vulnerable to extreme weather events (e.g., drought) and disturbance, such as livestock overgrazing (**Figure 1**). Desert grasslands in the American Southwest are typically net carbon sinks. With conversion to shrublands, arid lands tend to become net carbon sources (Barger et al. 2011), and adversely affect air quality by increasing dust loading and the concentration of volatile organic carbon compounds (see Section 4.20.2.3.2). Cases where shifts from grass to shrub dominance do not change the total amount of organic carbon in the soil pool have also been documented. In these instances, the spatial distribution of soil organic carbon (SOC) is strongly impacted, with SOC becoming concentrated beneath shrub canopies with very little SOC in bare soil gaps between plants. This shift in the distribution of SOC has important consequences for soil properties that feed back to influence the availability of water and nutrients to plants, animals, and microbes (see Section 4.20.2.2.1) and the nature of land surface–atmosphere interactions (see Section 4.20.2.1.1).

Desertification also poses a threat to inorganic carbon storage, which contains roughly 10 times more carbon than the amount in soil organic matter. When desertification reduces plant production, the amount of CO_2 respired into the soil and the abundance of microorganisms, which are partially responsible for the precipitation of $CaCO_3$, decline (Monger et al. 1991). In addition, desertification causes erosion and exhumes subsoil horizons. When wind and water erosion expose long-buried inorganic carbon to the geochemical environment at the land surface, $CaCO_3$ can break down and contribute CO_2 to the atmosphere (Serna-Perez et al. 2006; Tamir et al. 2011).

Threats to Future Trends in Carbon Storage

The net storage or loss of carbon in an ecosystem is the balance between carbon uptake by plants and carbon released by plant and microbial respiration. Because levels of soil organic matter are inversely related to mean annual temperature in many arid regions, increases in regional temperature would promote losses of soil carbon to the atmosphere, exacerbating increases in atmospheric CO_2. This accelerated carbon liberation might be compounded by declines in levels of carbon sequestration, which would decrease with decreasing rainfall. Grazing by livestock is the predominant land use in drylands. Excessive grazing is detrimental to plant productivity and can further accentuate declines in soil organic matter. Land management can contribute to the mitigation of radiative warming from atmospheric CO_2 by adjusting practices to increase or protect the amount of carbon (C) stored in soils and vegetation. In particular, stocking at sustainable levels to maintain desirable shrub:grass ratios, responding quickly and decisively to drought to avoid degradation, and developing and implementing technologies, such as appropriate plant materials, reseeding methods, and management guidelines to restore degraded areas could increase soil carbon storage at approximately 0.15 Gt year^{-1} over the next 100 years (Thomson et al. 2008). Although this level of potential C sequestration is relatively low per unit of land area compared to other land-use categories, the vast land area in drylands and strong positive correlation between increased sequestration and other desirable benefits makes sequestration worth pursuing. However, by far the most effective strategy, given the potential for desertification-induced losses of soil carbon in rangelands, is to develop tools, policies, and programs to identify arid lands at risk before they are seriously degraded, and to implement management to halt or reverse the degradation.

4.20.2.2 Provisioning Services

4.20.2.2.1 Water Quality and Quantity

An optimum quantity and quality of water are needed to maintain natural and human ecosystems. The way that land, water, and atmospheric resources in drylands are exploited or developed can have serious effects on ecosystem provisioning and regulating services related to water. Landscapes in drylands are organized into watersheds of different sizes, ranging from small headwater or upland basins to larger watersheds that encapsulate the valley floor. As such, watersheds are critical for water provisioning and use in the American Southwest. However, drylands are continually operating under conditions of limited water availability since evapotranspiration demand greatly exceeds low precipitation amounts. As a result, dryland ecosystems have evolved to maximize their efficient use of water, although episodes of drought or flooding can significantly alter the balance between water availability and ecosystem function.

Many landscape characteristics in drylands, including the spatial distributions of plants and animals, are shaped by the availability and distribution of water and the timing of its delivery. As a result, hydrologic conditions can vary substantially over short distances, with common occurrences of ephemeral channels and isolated perennial reaches fed by shallow groundwater or springs. Although these riparian features occupy less than 1% of the entire landscape, they have disproportionately large impacts on ecosystem productivity and biological diversity. Water availability and its influence on the landscape also have a direct impact on atmospheric conditions, which can lead to short- and long-term feedbacks to weather and climate (see Section 4.20.2.1.1).

The natural scarcity of water in drylands, coupled with the ever-increasing demands for water from rapidly expanding human populations, constitutes a major challenge in watershed management. Stakeholders affected by inadequate amounts and quality of water in drylands include ranchers and pastoralists (livestock), farmers (crops), ecologists (natural vegetation), and the public (recreation, wildlife, residents). As suburban or urban land uses proliferate, additional stakeholders include towns and cities (and their residents) who become important users of water, as agricultural or land-use rights are transferred. These stakeholders can also impact water in drylands through effects of grazing, mining, and urbanization activities on the natural landscape. Mining in the Southwestern United States in particular, has reduced water availability and impacted its quality in areas adjacent to and downstream of excavations.

Consequences of Desertification for Water Supplies

Desertification and the encroachment of woody plants into grasslands have direct impacts on the distribution of water and its quality within landscapes (Huxman et al. 2005). Since plant–water relations are bidirectional, a change in the dominant plant functional type can result in a myriad of impacts and feedbacks in the water, carbon, nutrient, and sediment cycles. Above and below ground plant characteristics affect local radiation, rainfall interception, root water uptake, soil moisture redistribution and litter and soil production, among other processes (**Figure 3**). Higher overall evapotranspiration losses occur when shrublands replace grasslands as a result of larger bare areas and greater plant water use efficiency of shrubs compared with grasses (Dugas et al. 1996). A greater demand for water by shrubs decreases overall water availability, with subsequent impacts on soil moisture, runoff generation, groundwater recharge, and transport of dissolved and particulate matter by water. Shrublands on sandy soils located on level topographic positions have been found to use most or all of the water from precipitation, while grasslands allow some deeper recharge. By contrast, the shift from grassland to shrubland on slopes and rocky soils can increase the amount of runoff and rates of water erosion. The connectivity of bare areas is typically greater in shrublands compared to grasslands, resulting in higher runoff and greater losses of nutrients and sediments (**Figure** 4(b)). This, in turn, translates into losses of soil fertility, the dissection of landscapes into rills and gullies, and increased sediment loads to downstream locations. The latter is the major cause of reductions in water quality in drylands. Interactions at the plant-to-patch scale in grasslands and shrublands aggregate to basins and watersheds, thus affecting water, nutrient, and sediment yield in broader areas.

Finally, dust emitted from desert regions, due to human activities and desertification, has the potential to impact mountain snow hydrology (Painter et al. 2010). Dust deposited on snow can significantly impact the amount of solar radiation absorbed by the snow, increase the rate of melt, and the rate at which meltwater is produced and delivered to river systems. These changes have the potential to impact water management and decrease the amount of water in major river systems (e.g., the Colorado River).

Threats to Future Trends in Water Quantity and Quality

Desertification adversely impacts water and sediment yield. Plausible changes in the intensity, duration, and frequency of precipitation events would accentuate these impacts. For example, the balance between grasses and shrubs which affects numerous ecosystem services is influenced by the amount, timing, and seasonality of precipitation and the size of rainfall events (e.g., Good and Caylor 2011). Should they occur, shifts between summer and winter precipitation or changes in the frequency of extreme storm events that deliver precipitation in short, intense pulses would be expected to tip the balance between grasses and shrubs either directly or indirectly via higher surface runoff, accelerated erosion, and changes in soil moisture and groundwater storage and recharge regimes. Higher temperatures would reduce the effectiveness of rainfall by increasing evaporative demands while concomitantly increasing water requirements and levels of physiological stress in plants and animals. This combination of increased runoff, increased soil evaporation, and reductions in plant performance would alter ecosystem rain-use efficiency.

Increases in convective storm intensity would increase the incidence and magnitude of surface runoff events and associated erosion. This, in turns, would lead to reductions in soil depth (critical for water storage) and fertility on upland sites and hence forage production (see Section 4.20.2.2.2) and ecosystem productivity (see Section 4.20.2.3.1). Particulates and nutrients in the sediments carried in these runoff events would be transported in ephemeral channels and eventually end up in playas or streams where water quality and the life span of man-made structures aimed at capturing water (e.g., ponding dikes, stock dams, and reservoirs) could be reduced.

4.20.2.2.2 Food and Fiber

Drylands contribute significantly to annual global food and fiber production owing to their extensive geographic extent on all continents. About 37% of the total annual global value of food and fiber production originates from drylands. One-half of this value is livestock products, primarily from extensive grazing of cattle, sheep, and goats, and one-half of livestock production globally each year is harvested from drylands used as grazing lands. In addition, about 10% of non-livestock food and fiber production (e.g., cereal grains and cotton) are produced from rain-fed systems in drylands. The remaining dryland food production originates from irrigated systems.

Of the two billion people living on drylands, about 800 million are farmers engaged in food and fiber production. Livestock ownership sustains about 675 million rural poor, predominately in the developing countries of the world. Estimates are that one in ten humans is involved in animal husbandry. Livestock are thus important economic assets and sources of income for rural people on all continents, except Antarctica. Although per capita demand for meat products may be at saturation levels within developed countries, demand for meat products is on the rise within developing countries, including China, Korea, and Brazil (Steinfeld et al. 2010). Demands for meat products are projected to increase 2–3% per annum. Globally, meat production is increasingly from intensive, confined systems, but extensive dryland production systems are the source of many of the animals that are ‘finished’ in confined systems and will continue to supply local meat demands and sustain rural economies, irrespective of a country’s economic status. Domesticated ruminants are well suited to both the biophysical and the socioeconomic conditions inherent to drylands.

In the American Southwest, the issue of food and fiber production from drylands has become less relevant over recent decades, despite growing global demands described above. The use of these lands for food and fiber production has diminished significantly from peak livestock numbers in the mid-twentieth century (Fredrickson et al. 1998). At present, it is common for public land allotments to be unused by livestock. These declines are mirrored across North America: cattle, sheep, and goat numbers (expressed as animal units) have declined by over 25% since 1979. In addition, recent rancher surveys reflect other characteristics of an industry in decline, including increased age of primary owners, smaller herd sizes, and growing importance of non-economic rationales for ownership, such as lifestyle and recreational motivations.

Consequences of Desertification for Food and Fiber

Desertification has had less of an impact upon food production than expected based on meat production. Ruminants have wide dietary preferences, and maintain inherent capacities to digest cellulose regardless of the dietary sources of forage. At least 10–20% of drylands globally are degraded through desertification processes, yet animal production has continued to increase. For example, the dramatic increases over the last two decades in goat numbers, averaging nearly 1.2 million additional goats around the world each month, in part reflect adjustments of meat production systems to altered landscapes and altered socioeconomic conditions. Certainly, degraded conditions due to overgrazing have caused significant reductions in capacities of drylands to produce forage with resulting losses in meat production at certain times on all continents, over the past century. However, the widespread impacts of overgrazing upon food production have likely been overestimated. In addition, within local regions where overgrazing has more recently resulted in degraded conditions, policies have often been implemented to constrain, if not outright ban, continued livestock grazing (Estell et al. 2012).

Threats to Future Trends in Food and Fiber

Degradation associated with land conversion and salinization is expected to influence drylands more so than livestock grazing. Farming on lands marginally suited for crops has been, and will likely continue to be, a major source of land degradation. Cereal production will likely need to increase by 0.5 billion tons per year over the next two decades owing to the demands of increasing human populations. In lieu of unit-area production increases on lands currently being cropped, this increase in crop production would be supplied by conversion of drylands. These drylands will be poorly suited for cropping, owing to thin, rocky soils on steep slopes, and low, variable, and unpredictable precipitation. A high rate of crop failure on such lands makes them susceptible to soil erosion and subject to high rates of abandonment.

The world food economy is being driven by continuing dietary shifts toward consumption of meat products. However, this shift will affect drylands differently than in the past. Impacts of the late nineteenth and early twentieth centuries were typically the result of excessive livestock stocking rates. The current settings and drivers are different. Given the saturation of per capita meat demand in developed countries, fewer livestock will graze drylands of Australia, North America, and Europe. Concurrently, as seen in recent decades, livestock numbers will continue to increase on the Asian and African continents where per capita meat demand continues to increase, although likely at a decelerated rate in coming decades. However, the demand for meat will be increasingly serviced by swine and poultry, and these more intensive livestock production systems will require increased reliance on and production of cereal grains. This demand for grains will drive conversion of drylands to cropland agriculture, and will place additional land area at risk for desertification. Reliance on traditional free-ranging livestock production systems will continue to decline, and will lead to shifts in the valuation of drylands for supplying other goods and services.

These shifting land uses represent opportunities to enhance the supply of other goods and services, but will require increased attention to valuing goods and services other than traditional food and fiber production. An often overlooked requirement of this valuation will be the need for methods to accurately assess benefits that result when management practices change to enhance the supply of these alternative goods and services.

4.20.2.3 Supporting Services

4.20.2.3.1 Plant Production, Carbon and Nitrogen Cycling

Primary production is a central process in the functioning of an ecosystem by which plants capture energy coming from the sun and transform it into chemical energy for microorganisms, animals, and humans. The flow of energy from the sun and back to outer space is coupled to the carbon cycle in most ecosystems. Plants capture carbon dioxide from the atmosphere and convert it to chemical energy (carbon based compounds, called carbohydrates) using light energy from the sun along with water and soil nutrients. This process is known as photosynthesis in plants, and the measurement of its magnitude represents ‘primary production’ in ecosystems. Primary production is estimated by assessing changes in plant mass over a known period of time (weight of biomass per unit area of land per unit of time (e.g., kg/ha/year)).

In drylands, plant production is limited by water availability, and nitrogen (N) is the second most important limiting factor. Average annual plant production increases with annual precipitation across a range of grasslands and shrublands located throughout the central and western United States. Dryland ecosystems with extremely low precipitation are most frequently limited by water availability, except during short periods of time after precipitation events when they can become limited by N availability. Water and N cycles are closely linked because their availability controls the activity of microorganisms and plants, which are sources and sinks of reactive N. However, the response of plants and microbes to water availability is not in synchrony because of their differential sensitivity to water availability (Schwinning and Sala 2004). For example, droughts negatively affect plant uptake more than they affect microbial mineralization. Thus, during dry periods, arid ecosystems tend to accumulate nitrate, which is one of the most common forms of mineral N in soils. During wet periods, however, mineral N concentration in soils is lower than in dry periods mostly as a result of increased demand by actively growing plants.

Primary production is a supporting ecosystem service (**Figure 1**) necessary for the production of all other services. Humans benefit from primary production indirectly because provisioning, regulating, and cultural services depend on it. In drylands, the major provisioning service is food production, and the growth of livestock and wild animals upon which humans depend is directly related to the abundance of plant biomass or primary production, and is related to forage production (see Section 4.20.2.2.2). Similarly, most regulating services depend on primary production that affects plant cover of the land surface, which in turn affects albedo and water balance and thus regulates climate (**Figures 2 and 3**; see Section 4.20.2.1.1). Primary production also affects disease regulation (see Section 4.20.2.3.5). For example, increased fall–spring precipitation associated with the El Niño phenomenon results in an increase in primary production in the American Southwest that leads to an explosion of deer mice (Peromyscus spp.), the rodent vector of the hantavirus (Yates et al. 2002). Primary production directly affects carbon sequestration (see Section 4.20.2.1.2) because it represents the major input of organic carbon into the relatively stable soil organic matter pool. Respiration of plant roots and decomposition of plant material provide the CO_2 needed to form pedogenic carbonates, which are a strong C sink in drylands (see Section 4.20.2.1.2).

Consequences of Desertification for Plant Production

Primary production is a relatively resilient ecosystem supporting service. However, even subtle changes in the nature of primary production can have major impacts on provisioning and regulating services. Desertification affects provisioning ecosystem services, such as food production, first by changes in species composition and species abundance. A replacement of palatable and grazing sensitive species by unpalatable, grazing resistant species has a relatively small effect on primary production (Peters et al. 2011), but may have a disproportionately larger effect on livestock production (Fredrickson et al. 1998). Grazing of herbaceous plants is often accompanied by the encroachment of unpalatable shrubs that feed back to reduce forage, and hence livestock production. In cases where perennial herbaceous plants give way to annual plants, production becomes less predictable and confined to narrow windows of time that correspond to the short life-span of annual plants (weeks to months). These short bursts of productivity can reduce soil water and nutrients needed by perennial plants that can be competitively displaced from the ecosystem. Furthermore, these annual plants produce far more biomass than animals can consume. When they complete their life cycle and die, they generate large amounts of fine, dry litter that is highly combustible. This increase in litter can dramatically alter the fire regime compared to historic levels (see Section 4.20.2.3.3). Grazing-induced reductions in perennial plant productivity and cover also expose the soil surface to erosional forces that then feed back to further accentuate degradation (see Sections 4.20.2.1.1 and 4.20.2.3.2). Erosion of the soil by wind caused by human activities and desertification processes that cause emission of nutrient-rich dust particles have the potential to change the biogeochemical properties of soils by reducing fertility (e.g., Okin et al. 2001; Neff et al. 2005; Li et al. 2007).

Planting of non-native grasses to restore desertified grasslands and improve forage production for livestock has been a long tradition in the drylands of North America. The US Department of Agriculture has maintained active research programs aimed at screening, breeding, propagating, and introducing plant materials collected from other parts of the world. In the Southwest United States, perennial grasses from Africa, notably Lehmann lovegrass and buffelgrass, were widely planted in the mid- to late 1900s. Since that time, they have expanded spatially to the point where they now threaten biodiversity across much of the region (see Section 4.20.2.3.4).

Threats to Future Trends in Plant Production

Because plant production is governed by both water and nitrogen, changes in one or both of these drivers in the future would impact patterns in production and the services that depend on it. Directional decreases in precipitation, such as an increase in the frequency, intensity, and duration of drought, would result in decreases in plant production. These decreases would be particularly so for perennial grasses and would likely make additional areas susceptible to shrub invasion and desertification (Fredrickson et al. 1998). Increases in precipitation, combined with sustained livestock grazing, would accentuate effects of dry periods on transitions from grasslands to shrublands. By contrast, directional increases in precipitation may have unexpected effects in shrublands that are commonly perceived as highly resistant to change. A 5-year wet period resulted in a nonlinear increase in grass production in shrublands as a result of grass seedling establishment and growth (Peters et al. 2011). Because large grass production was maintained even in subsequent dry years, this wet period may have initiated a state change reversal from shrublands to grasslands that has not been observed over the past 150 years. Subsequent wet periods are expected to result in similar state change reversals. Increase in nitrogen to these systems from atmospheric deposition would also favor grasses that are currently nitrogen limited, compared with shrubs, such as mesquite that can fix their own nitrogen.

Clearly, changes in land use have effects on regional climate (Pielke et al. 2011; Avila et al. 2012), as well as effects on plant production. Although conversion of grazing land to agricultural land through water redistribution may have positive short-term effects on plant production, the long-term impacts on water quality and quantity, and trade-offs with increasing human demands for water (see Section 4.20.2.2.1) may limit the feasibility of these land conversions in the future.

4.20.2.3.2 Air Quality

Air quality impacts all inhabitants of dryland regions. The atmosphere is comprised of gases, as well as, very small solid or liquid particles known as aerosols. One of the most obvious aspects of air quality is visibility, which is a function of both the amount and type of aerosols in the air. The most important contributor to low visibility in drylands is mineral dust, which is produced when strong winds strip particles from non-vegetated surfaces in the landscape, and a portion of those particles become suspended in the air column (Okin et al. 2006). Large dust storms result in significant reductions in visibility, and create hazards to both air and road travel (**Figure** 4(c)). Reports of major traffic accidents along roads and highways are common from dryland regions. Dust can also contribute significantly to vehicle and aircraft maintenance costs.

Dust can have a profound impact on human health (see Section 4.20.2.3.5). For instance, Coccidioidomycosis (known as valley fever) is a sometimes fatal disease caused by a fungus endemic to the American Southwest that is transported on dust (e.g., Kolivras and Comrie 2003). Desert regions with significant dust can frequently violate health standards for respirable material (PM10 and PM2.5, particulate matter less than 10 μm and 2.5 μm, respectively), and desert dust has been positively linked to hospitalization of children due to asthma.

Consequences of Desertification for Air Quality

Desertification often leads to either a reduction in vegetation cover or a reorganization of that cover so that the size of unvegetated gaps and amount of bare ground between vegetation increases. These larger bare gaps are more prone to wind erosion and the dust emission that accompanies it. Unvegetated areas made directly by humans, whether roads, construction sites, or off-highway vehicle tracks, also contribute to dust emission, particularly when the disturbance is aligned with the prevailing wind direction. Soil surface disturbance of natural desert stabilizers (biological and physical crusts, desert pavements) due to agricultural, recreational, and grazing activities has resulted in large increases in dust production in the Southwestern United States since 1850 (Neff et al. 2008). Drought, by reducing plant cover and production (see Section 4.20.2.3.1), can also result in large bare areas and hence increased dust emission. Aerosols and gaseous components in smoke significantly impact air quality and can be linked, in some cases, to desertification. For instance, throughout much of the Sonoran Desert, shrub communities that evolved in the near-absence of fire are being invaded by warm-season grasses that can sustain high enough fuel loads to result in wildfire (see Section 4.20.2.3.3) (D'Antonio and Vitousek 1992). In these areas, smoke and gas emissions due to fire would have been, in the absence of this form of desertification, a rare occurrence. Dust emissions following these fires would be elevated until vegetation cover is restored.

Finally, many desert plants are known for having strong scents, a common indicator of the emission of volatile organic carbon (VOC) compounds from their leaf surfaces. Mesquite and creosote bush are common shrubs that have increased throughout the American Southwest with overgrazing by livestock and drought that led to broad-scale desertification. These shrubs are strong producers of VOCs compared with grasses. In their gas phase, VOCs from desert vegetation can contribute to anthropogenic emissions and lead to air quality standards being exceeded. Furthermore, VOCs can produce liquid aerosols that reduce visibility while enhancing the longevity of GHGs and radiative forcing (see Section 4.20.2.1.1).

Threats to Future Trends in Air Quality

The two largest threats to air quality in drylands in the future are changes in land use and possible changes to drier conditions. Changes in land use that increase bare ground on soils susceptible to wind erosion would undoubtedly create an increased frequency of poor air quality in drylands. Similarly, an increase in periods of drought that reduce vegetation cover would lead to an increased occurrence of dust emission events.

4.20.2.3.3 Disturbance Regimes: Wildfire

Wildland fire is commonly perceived as a threat to human life, property, and, in some cases, ecosystem services. Many people believe that fires should be prevented and, if they do occur, that rehabilitation and restoration actions may be warranted. It is less appreciated that fire historically played a major role in maintaining ecosystems in their current, natural, or otherwise desired condition (e.g., Johnston and Klick 2012). Ecosystems are affected by fire at various levels of intensity and patterns of burning (e.g., within and among years and across landscapes). The fire regime, or the magnitude, temporal, and spatial characteristics of fire, partially defines many ecosystems. Like many other agents of natural disturbance (e.g., extreme weather events, pest outbreaks), fire regimes can promote biodiversity, heterogeneity, and dynamic ecosystem stability. Fire regimes are also a very strong natural selection factor that influences the evolution and distribution of species. When fire regimes are altered, populations, communities, and ecosystems can be affected along with the services they provide.

Role of Fire in Desertification with Consequences for Ecosystem Services

Dryland ecosystems have a characteristic fire regime that both affect, and are affected by, the composition and structure of vegetation. In grasslands of the American Southwest, the pre-Anglo-European settlement fire regime was one of moderate intensity surface fires carried by perennial grasses in late summer when plants were dormant and primary production (see Section 4.20.2.3.1) was at its peak 28 (**Figure** 4(d)) (McPherson 1997). Livestock grazing beginning in the mid-1800s, and landscape fragmentation and fire suppression activities during the mid- to late 1900s, reduced the amount and continuity of grass fuels and hence the frequency and extent of fires (Allen, 2007). With less fire, woody species expanded into areas where frequent fire previously excluded them, resulting in a decline in grasslands and an increase in areal extent of shrublands. As woody plant abundance increased, grass production further decreased, while bare ground increased, further reducing the probability that fire would start and spread, thus providing a positive feedback that reinforced the maintenance or increase in woody plant abundance (Ravi et al. 2007). The replacement of grasslands by shrublands following cessation of fire in drylands results in lower levels of primary production (see Section 4.20.2.3.1), lower carbon sequestration potential (see Section 4.20.2.1.2), and higher cover of bare ground; all of which feed back to influence the region's climate (see Section 4.20.2.1.1) and impact air and water (see Sections 4.20.2.2.1 and 4.20.2.3.2) resources.

By contrast, shrublands and savannas were historically characterized by less frequent and patchier fires compared to grasslands. Longer intervals between fires allowed shrubs and trees to establish and grow sufficiently large to survive surface fires. Removal of fine fuels by livestock grazing and suppression of fire had less dramatic effects on these fire regimes.

Threats to Future Fire Regimes

Fire alone may not be sufficient to maintain native perennial grasslands under all conditions. Fire regimes depend on fine-fuel production by grasses, and influence the capacity for grasslands to persist only if livestock grazing regimes, soils, and climate are conducive to the establishment and growth of perennial grasses. Threats associated with desertification that affect soil fertility and the distribution of soil nutrients, or that result in reduced soil moisture levels during the summer, can reduce grass productivity and cover, thus reducing fire frequency and intensity, and increasing the chances of woody plant encroachment.

Similarly, soil nutrient loss and horizontal homogenization in shrublands invaded by non-native grasses may prevent re-establishment of shrubs. Changes in the amount and season of lightning can also affect the frequency and seasonality of fire, and the balance of grasses versus woody plants. Landscape fragmentation can isolate patches of fuels, and limit the size and spread of wildfires; thus muting the potentially positive effects in maintaining grassland or negative effects in maintaining shrub steppe and woodlands. However, fragmentation may also facilitate the application of prescribed fire during the summer season by providing pre-established fuel breaks that make individual fires easier to manage. Increased nitrogen deposition and elevated concentrations of atmospheric carbon dioxide can promote the establishment and dominance of non-native plant species, which can affect fire regimes if they alter the structural and seasonal characteristics of fuels (Brooks et al. 2004).

In addition, invasions by non-native grass species have had tremendous effects on fire regimes. Non-native perennial grasses, such as Lehmann lovegrass and buffelgrass, and annual grasses, such as red brome, have increased the mass and continuity of fuels and decreased the time required for post fire fuels to return to conditions that can carry subsequent fire. These changes have increased the frequency and extent of fires in shrub steppe such that native woody species cannot persist and non-native grasslands now predominate. These conversions of vegetation types and fire regimes have concomitant negative effects on individual species and overall biodiversity (Ravi et al. 2009).

4.20.2.3.4 Biodiversity

Biodiversity refers to the range of variation found among microorganisms, plants, fungi, and animals. Biodiversity is typically measured using numbers of species in an area and how rapidly the identity of species changes over space and time. Biodiversity indirectly affects ecosystem processes, such as net primary production (see Section 4.20.2.3.1), decomposition (see Section 4.20.2.1.2), biological control of pests (see Section 4.20.2.3.5), and even physical processes affected by plants such as water and wind-driven soil erosion (see Sections 4.20.2.2.1 and 4.20.2.3.2). Biodiversity is also an important basis for sustenance, recreation, and spirituality for people who inhabit or visit drylands. Stakeholders with direct interests in biodiversity include hunters, naturalists, tourists, exurban homeowners, and ranchers. These stakeholders may have differing values for particular species comprising biodiversity, including species that are: game (mule deer, scaled quail), threatened with extinction (Chiricahua leopard frog, Chihuahua Scurfpea), pests (coyotes, woodrats, certain shrubs), regulators of ecosystem processes (termites, grasses), or recreation (native birds, wildflowers). These varying values guide how biodiversity is managed in drylands (see Section 4.20.2.4.1).

Consequences of Desertification for Biodiversity

Biodiversity in drylands is strongly influenced by the high variability in stress (e.g., temperature) and resource availability (e.g., water and plant production) over time and space, particularly when compared with other ecosystem types (Stafford Smith and McAllister 2008). Dryland species often have specific adaptations that allow them to tolerate or avoid resource scarcity and stress, and certain species are highly specialized to particular conditions. Land uses, including variations in grazing pressure, conversion of wildlands or rangelands to crop agriculture, and urbanization interact with environmental variability and species adaptations to cause changes in biodiversity. Of particular concern, desertification associated with past heavy livestock grazing has reduced grassland associated species when shrubs or bare ground dominate ecosystems (Archer 2010; Eldridge et al. 2011). Similarly, historically shrub-dominated ecosystems and their associated flora, fauna, and microorganisms were altered when invasive annual grasses become dominant (Ravi et al. 2009). In such cases, biodiversity of a specific functional group of organisms (e.g., ants or breeding birds) may be reduced or the identity of species may change with no net loss of species numbers at a local scale (**Figure 5**(a)). Often, however, certain species decline in abundance, so these species become the focus of biodiversity concerns and management efforts (**Figure 5**(b)).

Threats to Future Trends in Biodiversity

In general, the extensive loss of formerly widespread habitat types due to past agricultural practices or non-native species invasions focuses management attention on the preservation and restoration of currently rare habitat types and their dependent species, such as reducing shrub cover to promote open perennial grasslands in the Southwestern United States (Archer et al. 2011). New challenges to rare habitat types in drylands are also emerging, including increasing aridity, and solar and wind energy development that is increasingly focused in drylands, and conversion of the more humid portions of drylands to crop agriculture (see Section 4.20.2.2.2). Mapping, model-based forecasting, careful land-use planning, and monitoring will need to be carefully coordinated as such novel conditions expand in order to prevent the additional loss of biodiversity elements.

4.20.2.3.5 Disease, Pests, Pathogens

The fate of disease in a changing environment is a significant and complex question for scientists and decision-makers alike. For human disease, outbreaks and altered patterns of disease are linked to both biophysical and social factors as part of coupled natural-human systems. Infectious diseases, those that are transmissible and caused by pathogens such as viruses, bacteria, fungi, protozoa and parasites, are particularly susceptible to interactions between ecosystems and human-related changes in land use and cover. Often, these pathogens are associated with a vector species that is part of the transmission cycle. Diseases and human health issues of particular importance in the American Southwest include valley fever (*Coccidioidomycosis*), Hantavirus, plague, and West Nile virus.

Consequences of Desertification to Disease, Pests, and Pathogens

Disease and its outbreaks can be depicted in an epidemiological triangle, comprising the environment (e.g., habitat, climate), a host (e.g., humans), and a pathogen (e.g., malaria parasite). Where applicable, the middle of the triangle includes a vector (e.g., mosquito, rodents, and ticks) that connects all three points of the triangle (Comrie 2007). The impacts of planned or unforeseen interactions among natural and human systems can alter relations across the triangle. Amplified disease threats can

Figure 5 Biodiversity can be increased, decreased, or unchanged with desertification that depends on focal species of interest: (a) pronghorns (*Antilocapra americana*) at the USDA ARS, Jornada Experimental Range, USA, are considered of 'least concern' by the IUCN red list of threatened species, and (b) banner-tailed kangaroo rats (*Dipodomys spectabilis*) are ecosystem engineers of the native grasslands in the American Southwest that are considered 'near threatened' by the IUCN red list of threatened species as a result of desertification and shrub invasion. Photos credit: Andrea Campanella (New Mexico state University).

occur through new combinations of suitable conditions (e.g., restricted vector habitat, urbanization) leading to increases in the pathogen or vector populations or via greater host exposure. Importantly, disease outbreaks can also occur if key regulating services provided by the ecosystem (**Figure 1**) are diminished (Irwin and Ranganathan 2007). For example, desertification can change surface water availability, abundance of mosquito predators, and temperature, all of which affect the effectiveness of the mosquito as a disease vector.

Several kinds of regulating services provided by ecosystems are relevant to disease and pathogens in drylands. For example, riparian systems promote clean water by acting as a biofilter for fecal pathogens in streams that cause waterborne diseases. Ecosystems generally have checks and balances in place where predators maintain populations of vector species in dynamic equilibrium. These balances can be upset by processes such as desertification (MEA 2005). Thus, a reduction in regulating ecosystem services can create conditions that lead to proliferation of vectors as pests (e.g., ticks, rodents, and mosquitoes) and the pathogens they carry.

Vectors and pathogens often create problems that result from the proximity of humans to locations where regulating ecosystem services have been diminished or removed. Urban areas provide the most prominent set of examples where highly altered, simplified, or exotic ecosystems cannot self-regulate in natural ways. For example, mosquito habitat in cities is often associated with water for irrigation or rainwater that collects in and around human habitation. Because mosquitoes in these environments are not part of a naturally regulated ecosystem, the potential for unchecked growth in vector populations is large. A complementary example is human exposure to Hantavirus, where rodent populations surge following high rainfall and abundant food supply (Yates et al. 2002). In subsequent average or dry years, human exposure to the virus increases as infected rodents seek food close to human dwellings.

Threats (or Opportunities) to Future Trends in Disease, Pests, and Pathogens

The biggest opportunities for the spread of disease at local scales are from landscape changes that modify the habitat for pathogens and their vectors. At regional and continental scales, the range of pathogens and vectors is associated with extremes of temperature and precipitation (Comrie 2007), such as frosts or changes in timing and duration of wet–dry spells. An example is dengue fever, currently in northern Mexico, but not yet in the Southwestern United States. The mosquito vector *Aedes aegypti* is present in the Southwest, but the pathogen is not endemic. It is unknown whether dengue will expand northward if the region's temperature and moisture environments change. The trajectory for these kinds of shifts in ecosystem services is inherently complex, and depends on changes in human activity, as well as the biophysical impacts of desertification within the climate system.

4.20.2.4 Cultural Services

4.20.2.4.1 Esthetics and Recreation

Non-material benefits obtained from ecosystems represent cultural services (e.g., esthetic and recreational experiences, cultural heritage, sense of place; **Figure 1**). Cultural services include and are shaped by human perceptions and preferences, recreational experiences, interpersonal displacement, and tolerance levels, and conflicts and benefits accrued to individuals in a landscape. Human evolutionary history has instilled strong adaptive biases that influence current perceptions and preferences with respect to visual landscapes and biological needs (Ulrich 1977). These adaptive biases and bonds between humans and their environment are strong and inherited, and are the basis for the proposition that esthetic satisfaction stems from the spontaneous perception of, and interaction with, landscape features. Explicit inclusion of cultural services is thus a key, but under appreciated, component of effective natural resources monitoring and management.

Cultural services have intrinsic value but also play a central role in determining the ecosystems, which people are disposed to value and protect, or to degrade or develop for other purposes. Perceptions of cultural services can be an important, albeit intangible, factor in public support of resource use, management, and policy. Alternatively, landscape or social conditions can change to have negative effects on desired cultural services that lead to undesirable conditions, declining recreation experience levels, conflicts among stakeholders, and eventually degraded environmental conditions. For example, increasing use in Saguaro National Park (Arizona) with associated physical impacts and competition between recreational groups (horse riders and hikers) diminished the recreation experience for each group and forced land managers to close trails, thus resulting in reduced opportunities.

Cultural ecosystems services are less understood and explored than other services, and are more difficult to quantify. Cultural services provide for human physical, mental, spiritual, social, cultural, and economic well-being, all of which are determined by a variety of traditional and changing perceptions, beliefs, attitudes, behaviors, needs, values, and influences. The provision of cultural services must take into account past, present, and possible future influences of humans on ecosystems.

Cultural services depend heavily on the relationship between humans and their environments. Recreational experience, for example, requires landscape settings that meet certain expectations in terms of the services they provide. Landscape settings such as lakes, meadows, and mountains provide unique experience opportunities, and humans are linked to each setting for a variety of reasons. Wildlands provide opportunities to explore and engage in nature, and to derive historic, spiritual, esthetic, and educational values. Cultural services in wildlands are observed in different ways: backpackers seek solitude, commercial outfitters earn income, mountain climbers seek danger and risk, and naturalists derive satisfaction from seeing and identifying plants and animals. Ecosystems providing cultural services also generate broader public support for conservation management. For example, the Cabeza Prieta Wilderness Area is Arizona's largest wilderness area, but is visited by very few humans. This primitive wilderness area is a symbolic refuge of nature that some suggest should be preserved and protected for inherent ecological, esthetic, and symbolic value. There is cultural value to many in knowing this type of landscape continues to exist.

Consequences of Desertification for Cultural Ecosystem Services

If desertification continues, there would be dramatic threats to the quantity and quality of cultural services available in drylands. With changing biodiversity (see Section 4.20.2.3.4 Biodiversity), the loss of wildflower production could result in lost recreation opportunities and the overall quality of the recreation experience. Increased human-related impacts, such as social trail and recreation site impacts would provide increased opportunities for invasive and non-native plant species.

Threats and the Future of Esthetics and Recreation

Significant threats to cultural services are associated with human use impacts and reductions in recreation opportunities. High quality recreation experiences often decline with increasing human population densities. Crowding, excessive numbers of visitors, and their associated impacts coupled with harsher environmental conditions affect the ability of these systems to sustain cultural services. For example, increased human use along the US – Mexican border in Organ Pipe National Monument in the Sonoran Desert, Arizona, has already led to a proliferation of trails and traffic on these fragile landscapes (**Figure 6**) (Sharp and Gimblett 2009). An increase in temperature and water stress on plants and animals would exacerbate the degradation from current human-caused impacts. The extent and severity of impact in disturbance-sensitive drylands suggest some of these environments may never recover (Sharp and Gimblett 2009). Climate impacts cultural services: weather influences visitor experiences and affects recreation choices, utility maximization, and net amenity benefits. Summer and winter season lengths determine the availability and quality of certain recreation opportunities, such as hunting, fishing, bird watching, and scenic viewing.

A critical challenge will be to provide cultural services, while at the same time balancing the protection of rapidly changing, declining, or degrading natural resources. A clear set of management objectives will be needed within the context of the many environmental changes underway (Cole et al. 2008). A more holistic paradigm that explicitly identifies and comprehensively incorporates cultural services is required. One such approach

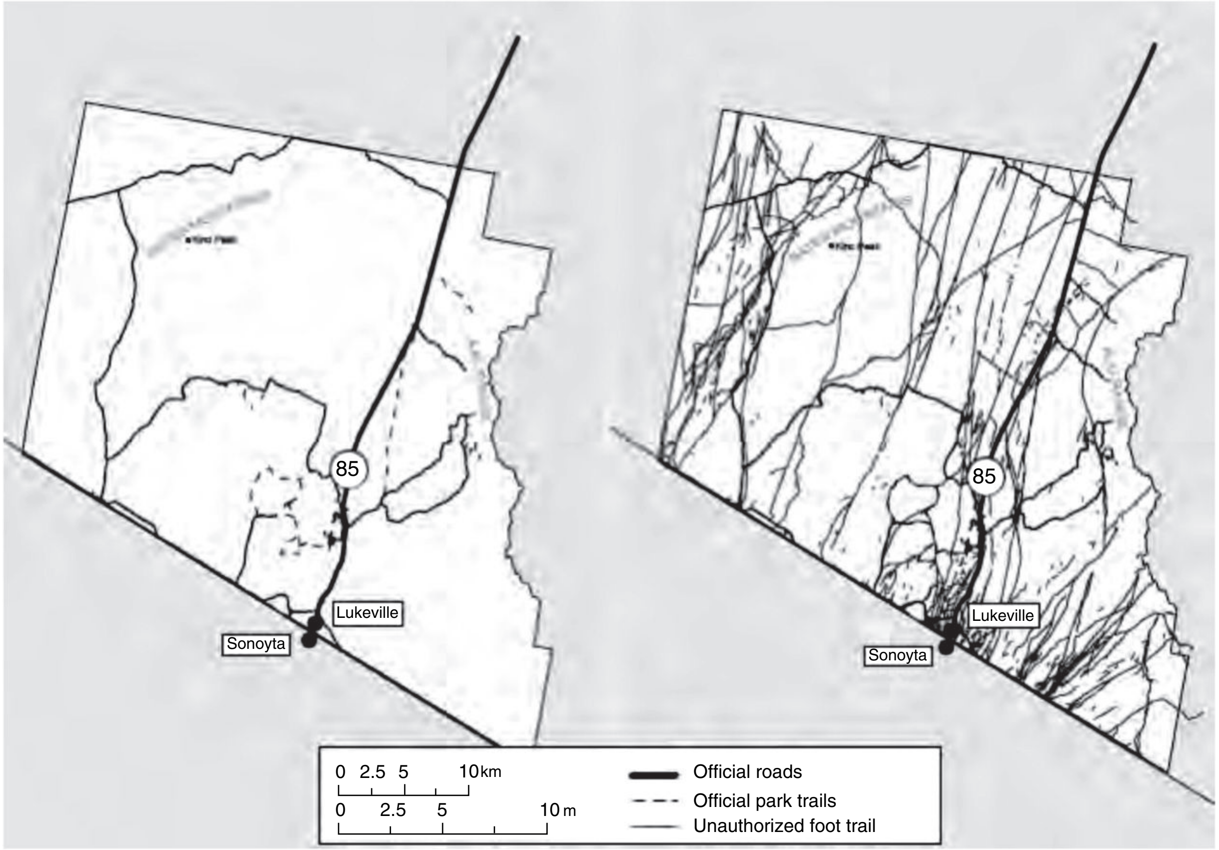

Figure 6 Increased human use along the US – Mexican border in Organ Pipe National Monument in the Sonoran Desert has led to a proliferation of trails and traffic on an already stressed landscape. Left: Official roads and recreational trails within Organ Pipe Cactus National Monument boundaries. Right: Official routes overlain with unauthorized routes that have resulted in severe loss of vegetation, erosion, unnecessary widening, gullying throughout Organ Pipe. These unauthorized routes will take years, if ever, to recover from such impacts. From Sharp, C., and R. Gimblett, 2009: Assessing border-related human impacts at organ pipe cactus national monument. *Conservation of Shared Environments: Learning from the United States and Mexico*, L. Lopez-Hoffman, E. D. McGovern, R. G. Vardy, and K. W. Flessa, Eds., University of Arizona Press, 226–40. (Permission granted from University of Arizona Press to publish figure: 12-1-2011.)

couples human and natural systems to rules governing land-use decisions, ecological models of landscape change, and decision support systems mimicking local landowners, recreational users, and resource management agencies (Scott et al. 2010a,b). This ongoing project attempts to understand complex utilitarian processes in human-dominated, semi-arid river systems and seeks to define the linked influences of climate, hydrology, societal practices and esthetic values, and any changes over time – on the social and ecological resilience of riparian corridors of two desert river systems: the Rio Sonora in Mexico and the San Pedro River, which originates at the same watershed boundary in Mexico, but flows northward into Arizona. Improved understanding of these complex processes provides a foundation for exploring what types of human occupancy and resource use may be possible, given climatic constraints set by a semi-arid ecosystem. In emphasizing the riparian-corridor ecotone, this project is exploring the nature and extent of combined societal and hydro-ecological changes under differing scenarios.

Public lands and protected areas, in general, are receiving a greater level and diversity of human activities and total visitation use than in historical times. This increase in demand leads to the question of whether public lands will have the ability to provide high quality cultural services now and into the future. Maintaining high quality cultural services, while protecting ecosystem integrity, remains at the heart of many contentious, confrontational, and highly scrutinized land-use planning and management processes that will continue into the future.

4.20.3 Potential Actions for Mitigation

4.20.3.1 Can Payments for Ecosystem Services Mitigate Desertification?

The growing awareness of the value of ecosystem services to society, and the increasing concern about threats to their continued provisioning, is catalyzing a new paradigm – viewing ecosystems as assets to be managed. As discussed above, drylands in the American Southwest provide a diverse array of services that support human life, food and fiber, clean drinking water, climate regulation, recreational experiences, wildlife habitat, and others (Havstad et al. 2008; Skaggs 2008). With the notable exceptions of food and fiber, the rest are public goods that have remained largely outside economic markets. Historically, the Farm Bill and other government programs have provided incentives to landowners for the protection of public goods. In the last decade, more and more conservationists, landowners, and natural resource managers are considering the concept of 'Payments for Ecosystem Services' (PES), as a way of providing market-based incentives to protect these goods. The objective of this section is to define PES and describe how it might be used to create incentives for preventing desertification and protecting the non-market goods provided by drylands. The questions addressed are: What types of PES programs are there and how they might be used to mitigate desertification? What are the short-term prospects for implementing PES programs in the American Southwest? And finally, given the vast public lands in the Southwest, how can PES be implemented on these lands? Payments for ecosystem services are market-based approaches in which users of ecosystem services directly compensate providers (i.e., landowners and managers) for their protection and supply. PES combines a positive incentive (if you improve and protect a resource, you can get paid by others to do so), with a negative incentive (if you impact a resource, you must or should pay for it) (Goldstein et al. 2011). Further, PES places the responsibility to pay for and protect ecosystem services on the individuals and private sector entities using the services. Ideally, PES should create payments for measurable outcomes (e.g., tons of carbon dioxide sequestered, volume erosion reduced, acreage of invasive vegetation removed) in contrast to government programs that provide incentives for changing management practices (e.g., grants for installing a fence to protect a waterway (CEAP 2011; Briske 2011)).

There are four types of PES programs that could be used to minimize or mitigate desertification in Southwestern grasslands. First, carbon programs provide payments to landowners and managers for undertaking management practices that reduce the loss of plant and soil carbon stocks (see Section 4.20.2.1.2). Second, water programs pay both upstream private landowners and public land managers for controlling erosion and grazing in order to promote higher air quality (see Section 4.20.2.3.2) and increase the quality and quantity of water delivered downstream (see Section 4.20.2.2.1). Third, biodiversity programs provide payments to landowners for the protection and/or restoration of a specified amount of habitat for target species (see Section 4.20.2.3.4) – such practices could include actions to mitigate desertification. Finally, there are bundled payments that combine carbon, water, and biodiversity benefits.

All programs require one of three market vehicles. First, compliance markets are created by regulation (e.g., Endangered Species Act, Clean Water Act). Second, voluntary markets occur when entities participate of their own volition – typically businesses to burnish a 'green' corporate image or private groups wishing to become 'carbon neutral.' Third, government-mediated payment programs (e.g., Farm Bill) use public funds to pay landowners for protecting or enhancing ecosystem services.

4.20.3.2 What Are the Prospects for PES in the US Southwest?

Despite the keen interest around the world in implementing PES programs, there are very few examples in arid regions and fewer yet in the Southwestern United States (Goldstein et al. 2011). Several years ago, observers of PES likely would have considered carbon programs to offer the greatest promise. However, failure to enact cap and trade (a federal regulatory driver for a nation-wide carbon offset program) led to the closures of the Chicago Climate Exchange in 2010 and its Sustainably Managed Rangeland Soil Carbon Sequestration Offset Project (Gosnell et al. 2011). Biodiversity markets in the form of mitigation banks to protect species habitat offer some promise: according to a recent report (Madsen et al. 2010), the habitat of at least 119 species in the United States is protected by mitigation banks. Arguably, the greatest promise for the Southwest lies in water programs, where municipal utilities enter into contractual agreements with upstream landowners or managers. An example of the potential for PES to align the interests of ecosystem service users and public land managers is the recently formed partnership between Denver Water, the utility that serves the city and surrounding suburbs, and the US Forest Service. Denver Water recently entered into a 5-year, $33 million partnership with the Forest Service to fund erosion control and wildfire prevention activities in its publicly managed upstream watershed. While some have questioned why the utility should pay a federal agency, the organizations argue that Denver Water is paying for additional land management practices specifically designed to protect and enhance water quality. Similar programs have been discussed in locations in the Southwest.

To date, there are few concrete examples of PES being used to combat desertification and degradation of drylands in the Southwest. In the absence of federal regulation on greenhouse gas emissions, it seems unlikely that carbon markets will emerge as a tool to mitigate dryland degradation, though state-level efforts (particularly in California) are continuing to keep some opportunities open. As biodiversity and water-based PES programs expand across the United States, it will be important for all stakeholders, land managers, private owners, civil society, and academia to carefully evaluate the opportunities that PES provides, and to tailor programs to meet the interconnected goals of preventing and mitigating desertification with protecting ecosystem services.

4.20.4 Recommendations for Land Managers, Policymakers, and Other Stakeholders

The effects of desertification and the threat of future effects upon ecosystem goods and services provided by drylands have important implications and lessons for land managers, policymakers, and other stakeholders who can be impacted. At the center of these implications is the knowledge that using general principles, even if derived from thorough research and peer reviewed analyses, will have limited application to any specific landscape and any specific emerging threat to any combination of goods and services. Actual management practices applied or policies implemented will have to be contextualized to the specifics of a landscape. For example, research may have identified the typical capacity of an ecosystem to produce a sustainable level of a particular good, such as livestock products. However, the vagaries of climatic drivers and resulting primary production for a particular ecosystem will negate the application of that average capacity to any specific time frame. In addition, generalizations based on past or recent research and experience may be irrelevant for ‘novel ecosystems’ developing under future conditions. Management programs need to be agile. Management actions need to be increasingly adaptive, and the policies supporting or constraining those actions need to be sufficiently flexible to readily accommodate adaptive adjustments.

Recognition of the need for adaptive management and flexible policies impacts the general principles that guide management. In the past, extraction of combinations of goods and services from drylands was guided by the principles of proper limits to use by livestock, proper distribution and timing of this use across landscapes, and proper types of livestock matched to a landscape and its forages. However, specific uses and combinations of uses change over time. Reductionist science has serious limits in identifying proper uses and combinations of uses for all landscapes in dynamic environments with numerous changing and interacting drivers. These principles, employed ineffectively on all continents for the past century, now need to be replaced.

Principles guiding resource managers need to be based on the simple concept that the central element to all of these goods and services, threatened or not, is the basic commodity of land. Within this concept is the recognition that ‘land’ is heterogeneous on many levels, and management principles and policies need to be designed and implemented based on this knowledge. The principles guiding management actions and policies should be rooted in the technology that classifies land based on similarities and differences with respect to climate, soil, landscape position, prior histories of management, and inherent vegetation dynamics – the ecological site and its description (Bestelmeyer et al. 2009). The cardinal principles of land management are then the proper descriptions of a site’s (1) potential to provide goods and services (which may be predicated on prior history), (2) current status, (3) suite of possible future trajectories in response to management practices and environmental conditions, and (4) monitored responses to those practices and conditions. These principles are very different than those utilized in the past, and the prior principles certainly contributed to the threatened and degraded conditions currently in existence.

Two key issues emerge from the recognition of the need for a new set of guiding principles. First, the successful application of these principles requires that institutions of management and policy improve their ability to learn from and adapt to the information derived from site-specific responses. Management practices, and the policies that guide them, need to be redesigned to dynamically accommodate specific lessons learned. These institutions need mechanisms where they can be informed by data and associated analyses. These mechanisms will require that landscapes have diverse and detailed data layers that are accessible, transparent, timely, and suitably described by metadata (Peters 2010). The infrastructure to support data-informed management actions and policies is not yet appropriately interactive and integrative, but these barriers can be overcome.

Second, conducting science to collect and organize data to inform land management and policy will require considerably different methodologies than used in the past. Issues related to climate change and desertification have forced ecologists and most resource managers to quantify patterns and processes at spatial scales more extensive than those addressed previously: how landscapes, land surfaces, and the atmosphere interact across a broad range of scales. This new science includes, but goes far beyond, the traditional highly controlled experimental designs of our reductionist past. It recognizes the need for research to (1) span multiple levels of organization in ecological hierarchies (reductionist approach) balanced by research aimed at understanding how mechanisms and processes at a given scale play out at broader scales over longer times (holistic approach), and (2) be interdisciplinary. For example, it has been stated that soil science has been “brilliantly informed by reductionist physics and chemistry, poorly informed by biology, ecology and geography, and largely uniformed by the social sciences” (Swift 1999). The science challenge now is less controlled, much more variable, and yet much more applied (Sayre et al. 2012). It is a science that employs management as an experimental, hypothesis-testing tool, e.g., the scientific method is applied in the testing of the effects of management practices as they are applied, or have been applied, in the field. It is a science that provides the types of data that can inform both management actions and policies geared toward heterogeneous landscapes under dynamic drivers, and that can learn and adapt as conditions warrant.

Finally, given the uncertainty of future climatic conditions, continued spread of exotic organisms, increasing global demand for an array of goods and services, and impacts of other drivers, it is important that policy makers and managers maintain and utilize mechanisms that can inform and focus science priorities. One possible mechanism to employ is future plausible scenarios generated by science-based models, worst-case historical and recent paleo–conditions, and sequences of events developed from linking together subsets of extreme events (such as the two most extreme droughts in the historical record placed in sequence). This mechanism can both prepare and direct management and policy actions. These scenarios can then be refined and employed in management and policy, and thus serve to maintain communication among scientists, policy makers, and managers relative to information needs and their relevance to the emerging problems of the future. A key recommendation for policy makers and managers is to more strongly employ and maintain linkages with scientists in shaping and focusing their priorities and their hypotheses to be tested.

4.20.5 Summary

Desertification, the broad-scale conversion of perennial grasslands to dominance by annual plants or xerophytic shrubs, and the attendant consequences to ecosystem services, has affected arid and semi-arid regions globally over the past several centuries. This state change is expected to continue in the future. It is generally well recognized that desertification is a cumulative threat that explicitly includes both climatic (e.g., drought) and land-use drivers (e.g., livestock overgrazing and inappropriate conversions of rangeland to cropland). However, a basis for ranking the relative importance of these drivers is lacking for many locations. In addition, the emergence of additional drivers (e.g., non-native forbs and grasses) modifying historic fire regimes will result in even more complex dynamics in the future. Questions remain: (1) How do these multiple drivers interact through time and space to influence grass–shrub dynamics? (2) When is the region's climate versus land use expected to be the primary driver governing ecosystem dynamics? (3) Where are management actions expected to be the most effective given variability in climate? (4) How would specific ecosystem services be impacted, and (5) What are trade-offs in positive versus negative effects when considering bundles of services?

Clearly, climate can have unanticipated effects, in particular for dryland regions with low and variable precipitation and high temperatures in the growing season. However, any change in climate statistics would be operating across diverse landscapes that include a mosaic of human-dominated and natural states, each governed by different drivers and susceptible to different threats. Accounting for the separate and interactive effects of these threats on grassland–shrubland transitions will be necessary as we move forward into a difficult to predict, if not unknown, environmental world.

Glossary

Additive effect A type of cumulative impact when the combined impact of multiple stressors is equal to the sum of the impacts of individual stressors.

Antagonism A nonadditive, mitigative interaction ('anti-synergy') between multiple stressors that occurs when the combined impact of these stressors is less than the sum of the impacts of individual stressors.

Community disassembly The process of nonrandom species losses and declines that can affect ecosystem structure and function.

Cotolerance The positive correlation between a species' tolerance to one stressor and its tolerance to another stressor that can reduce the cumulative impact of multiple stressors.

Recovery The ability of an ecosystem to 'bounce back' to a state that is functionally similar to its original state after a disturbance.

Resilience The capacity of an ecosystem to absorb disturbance without shifting to an alternative state and losing function and services. Resilience encompasses two separate processes resistance and recovery.

Resistance The immediate ability of an ecosystem to absorb disturbance without changing state or function.

Stressor Any environmental or biological impact that exceeds natural levels of variation to cause a negative ecological response.

Synergy A nonadditive interaction between multiple stressors where the combined impact of these stressors is greater than the sum of the individual impacts.

Coral reefs are among the most biodiverse ecosystems on the planet and provide immense ecological and economic benefits that contribute to the welfare of millions of people (Moberg and Folke 1999). However, coral reefs are also one of the most vulnerable ecosystems to climate change (Hughes et al. 2003, Hoegh-Guldberg et al. 2007). This may seem puzzling because modern scleractinian (reef-building) corals have experienced and survived extreme variation in ocean conditions (including multiple mass extinction events) since their appearance in the Middle Triassic, approximately 240 millions of years ago (Stanley 2003). However, the current climate-related coral reef crisis is unique for two reasons. First, the rates of increase in atmospheric carbon dioxide concentrations associated changes in carbonate availability, and seawater acidity are simply unprecedented (Knoll et al. 2007). Second, these rapid environmental changes are occurring against a background of other widespread human-induced disturbances, such as fishing, coastal runoff, pollution, and invasive species, which may ultimately stress corals to the brink of extinction (Carpenter et al. 2008).

Understanding the cumulative impacts of stress on ecosystems and rethinking our management philosophies to explicitly incorporate multiple, interacting stressors is a critical challenge for twenty-first century conservation (Paine et al. 1998). In this respect, coral reefs are unfortunately a model ecosystem to evaluate the cumulative impacts of multiple stressors and how to manage for them (Darling et al. 2010). In this chapter, we briefly review the impacts of climate change on coral reefs and consider how climate change-induced coral bleaching can interact with local, human-caused stressors affecting these species-rich ecosystems. Central to current thinking about the management of coral reefs is the concept of resilience. We outline the conventional view of coral reef resilience to climate change, and offer an alternative that considers how changes in coral community structure, resulting from local stressors, can affect resilience. Finally, we consider the implications of these two resilience frameworks for coral reef management and the role that no-take Marine Protected Areas (MPAs) can play in a changing climate. We conclude that there is hope for the survival of coral reefs. However, the cumulative impacts of climate change and local human impacts may motivate a new agenda for coral reef conservation.

4.21.1 Impacts of Climate Change on Coral Reefs

Increasing atmospheric CO_2 and climate change are warming and acidifying the world's oceans. This future 'hot and sour soup' (Palumbi 2010) will have widespread consequences for scleractinian corals (Hoegh-Guldberg et al. 2007). Over the past century, average global sea surface temperatures (SSTs) have risen by 0.6 °C and temperature anomalies, i.e., deviations from long-term temperature averages, are occurring more frequently (Hoegh-Guldberg 1999; Hoegh-Guldberg and Bruno 2010). Warmer than normal SSTs can result in coral bleaching, caused by a breakdown in the relationship between corals and the endosymbiotic unicellular algae (zooxanthellae) that provide corals with most of their metabolic requirements. Thermal stress can trigger the expulsion of the colorful zooxanthellae from their coral hosts, which can cause the coral to turn white or 'bleach' (Hoegh-Guldberg 1999). Corals may recover from short-term bleaching, by adopting new zooxanthellae, which are sometimes more thermally resistant than the ejected strain (Baker 2001 Baker et al. 2004; Berkelmans and Van Oppen 2006), but the physiological stress of bleaching interrupts coral growth, reproduction, and may make recovering corals more susceptible to diseases (Harvell et al. 2002; Bruno et al. 2007). Sustained SSTs 1 °C above average can lead to mass bleaching, which can affect hundreds to thousands of kilometers of reef area and result in widespread coral mortality (Hoegh-Guldberg 2005). The loss of live coral cover and architectural complexity on bleached reefs can have substantial ecological and economic consequences, affecting a broad range of coral reef fish, invertebrates, and the fisheries they support (Pratchett et al. 2008).

In addition to warming the oceans, climate change is fundamentally altering ocean chemistry. Approximately one-third of atmospheric CO_2 emissions are absorbed by the oceans and dissolve to reduce ocean pH, effectively increasing the acidity of seawater (Pelejero et al. 2010). Over the past 150 years, sea surface pH has dropped by 0.1 units and sea surface acidity has increased by ~26% (Doney et al. 2012). This altered ocean chemistry can reduce the ability of corals to build their calcium carbonate skeletons and can also disrupt critical metabolic processes, such as gas exchange and reproduction (Kleypas and Yates 2009; Pelejero et al. 2010). Ocean acidification can also decrease the productivity of calcifying crustose coralline algae, the preferred settlement substrate for juvenile corals, which may disrupt important cues for coral recruitment (Anthony et al. 2008; Doropoulos et al. 2012). Acidification is expected to broadly alter coral communities. A glimpse of such impacts is provided by 'champagne reefs,' such as those found in Papua New Guinea. These reefs persist in naturally acidic waters caused by the bubbling of carbon dioxide released from volcanic seeps in the substrate; the pH at acidic sites – around 7.8 – is consistent with some scenarios of ocean pH by the end of this century. The naturally lower pH reef communities are depauperate in coral diversity and have fewer structurally complex framework-building corals, less crustose coralline algae, fewer juvenile coral recruits, and a higher cover of fleshy macroalgae and seaweeds compared to adjacent reefs with 'normal' 8.1 pH (Fabricius et al. 2011). Thus, ocean acidification may profoundly affect the structure and function of coral reef benthic communities. Coral reef fishes will also be affected by altered ocean chemistry, if the results of laboratory and field experiments materialize in natural populations. For example, high CO_2 conditions can impair the cognitive and sensory abilities of juvenile fishes by interfering with neurotransmitter function (Nilsson et al. 2012), which can affect their settlement (Munday et al. 2009) and predator avoidance behavior (Dixson et al. 2010). Such altered behavior may drastically reduce juvenile survival and recruitment, which is expected to have wide-ranging consequences for the sustainability of fish populations in a more acidic ocean (Munday et al. 2010).

Ocean warming and acidification are only two of the many manifestations of climate change. Other potential influences include sea level rise and changes in storm regimes caused by warmer SSTs (Hoegh-Guldberg & Bruno 2010; Doney et al. 2012). However, these effects are expected to be more benign than the fundamental threats to coral survival posed by a warmer and more acidic ocean. Nevertheless, while climate change is an unprecedented threat, it is just one of many threats that jeopardize coral reefs.

4.21.2 Coral Reefs and Cumulative Impacts

In addition to climate change, coral reefs are impacted by a multiplicity of local stressors. These include fishing, which removes species with important ecological functions, sedimentation from coastal and watershed development, eutrophication from agricultural and urban runoff, and invasive species, which can outcompete or prey upon native species. More than half of the world's coral reefs are faced with high levels of human activities (Halpern et al. 2008). The cumulative impacts of local and global stressors have resulted in widespread losses of live coral cover (Gardner et al. 2003; Bruno and Selig 2007) and an elevated risk of extinction to one-third of all reef-building corals (Carpenter et al. 2008). Shifts have been observed in the structure and diversity of human-impacted coral communities (McClanahan et al. 2007a, 2007b; Alvarez-Filip et al. 2011), such as the flattening of coral reef habitats when architecturally complex coral species are gradually replaced by smaller, simpler taxa (Alvarez-Filip et al. 2009). Such fundamental changes in the reef framework can have cascading consequences for reef fish and invertebrate abundance and diversity, which depend on reef habitat for food and shelter (Graham et al. 2006; Pratchett et al. 2008; Messmer et al. 2011). The cumulative impacts of multiple stressors are undoubtedly already affecting the ecosystem functions and services of coral reefs, which are estimated to be worth more than $30 billion annually (Cesar et al. 2003). The impacts on tourism, coastal protection, and fisheries are the most obvious. For example, the 1998 mass coral bleaching event in the Indian Ocean resulted in an estimated $706 million to $8.2 billion in economic damages (Wilkinson et al. 1999). Intact coral reefs have high vertical relief, which effectively dissipates the wave energy reaching the coastline, protecting beaches and buildings from storm surges and tsunamis (Sheppard et al. 2005).

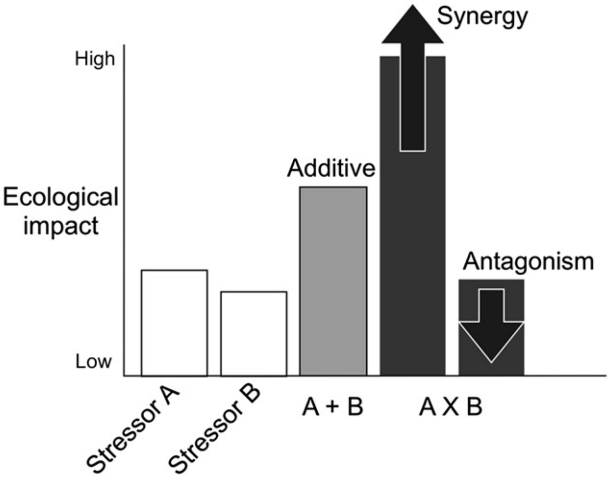

Figure 1 The cumulative ecological impact of two stressors can result in simple additive effects, synergies, or antagonisms. Synergies and antagonisms are examples of 'ecological surprises,' where the combined impact of two or more stressors is greater than (synergy) or less than (antagonism) the simple additive sum of the two individual stressors.

The loss of healthy reefs may therefore limit the protection they can provide to coastal communities (Barbier et al. 2011). Declining coral reef fish and invertebrate populations stemming from declines in the quality or availability of reef habitat will have economic consequences for coral reef fisheries, and the millions of people in developing countries that depend on coral reef resources for subsistence and livelihoods (Pratchett et al. 2008; Barbier et al. 2011). There are therefore very convincing ecological and economic reasons to understand how multiple stressors interact to produce such drastic effects, and whether there might be ways to manage stressors to mitigate these interactions.

There is increasing concern that the decline of coral reefs (and other ecosystems impacted by multiple stressors) has been driven by synergies, nonadditive interactions between two or more stressors characterized by a combined impact that is greater than the simple sum of the individual impacts (Folt et al. 1999; Breitburg and Riedel 2005) (Figure 1). In effect, synergies occur when the impact of two or more stressors is greater than the sum of the parts. Synergies are one type of unpredictable 'ecological surprise' that can accelerate biodiversity loss (Brook et al. 2008) and impair the functioning of marine ecosystems (Paine et al. 1998; Hoegh-Guldberg and Bruno 2010). However, the presence of multiple stressors does not necessarily imply that synergies should be expected. For example, the impacts of multiple stressors can be mitigated by antagonisms, which are interactions where the combined impact is less than the sum of the individual impacts (Figure 1). The combined impact of multiple stressors can also be simply equal to the sum of the impacts of individual stressors, resulting in a straightforward additive effect (Folt et al. 1999; Breitburg and Riedel 2005) (Figure 1). Two recent meta-analyses of hundreds of published studies, evaluated the combined impacts of multiple stressors in terrestrial and aquatic ecosystems, suggest that synergies, antagonisms, and additive effects may be equally common when two stressors are acting (Darling and Côté 2008; Crain et al. 2008). However, the addition of a third stressor can often, though still not always, result in a synergistic outcome (Crain et al. 2008).

Evaluating the cumulative impacts of multiple stressors is critical to forecast future ecological change on coral reefs and effectively manage the combined impacts of multiple stressors. One of the greatest scientific uncertainties concerning the decline of coral reefs is how local human impacts (i.e., fishing, pollution) will interact with global climate change (Knowlton and Jackson 2008). It is generally assumed that local human impacts will erode the ability of coral reefs to resist the impacts of climate change and that coral reefs already exposed to human disturbances will be less resilient to climate change, and could 'tip' into a degraded and less desirable coral-poor state sooner than more pristine reefs. Thus, enhancing resilience by reducing the impacts of local stressors is deemed by many to be crucial for conserving coral reefs in the face of global climate change.

4.21.3 What Is Resilience?

The concept of resilience now underpins much of the thinking about the management of coral reefs. It was first proposed by Holling (1973), who defined resilience as "a measure of the persistence of systems and of their ability to absorb change and disturbance, and still maintain the same relationships between populations or state variables." Holling explicitly recognized that ecosystems are dynamic, spatially and temporally heterogeneous, and can exist in multiple alternative states depending on environmental conditions. For example, temperate lakes in North America and Europe can persist in a state of clear water or in an alternative state of high turbidity depending on the input of nutrients and the presence of predatory fishes. Similarly, savannas and grasslands may either be grass-dominated or shrub-dominated, depending on the intensity of grazing (Folke et al. 2004). Coral reefs are no different. Under certain conditions, coral reefs are 'coral-rich,' with a high cover of coral and a low cover of macroalgae, but in altered environments they can transform, sometimes quickly, into coral-poor reefs with extensive stands of fleshy algae (Bellwood et al. 2004). Other alternative states are also possible for coral reefs, such as assemblages dominated by sponges and/or soft corals (Norström et al. 2009). Resilience may therefore be functionally defined as the capacity of an ecosystem to absorb and adapt to shocks and disturbances without fundamentally shifting into an alternative state (Scheffer et al. 2001; Hughes et al. 2010).

An ecosystem may be resilient for two reasons. On the one hand, an ecosystem may be resistant to a given perturbation. Carpenter et al. (2001) defined resistance as the amount of external pressure needed to bring about a given amount of disturbance in a system. For example, through differing species compositions, with some assemblages made up of species that can withstand greater magnitudes of the perturbation of interest than other assemblages. On the other hand, two ecosystems may have similar resistance to a given perturbation, but may differ in their potential for recovery, that is their ability and/or swiftness to return to a state that is functionally similar to the pre-disturbance state. Functional similarity is the operative term here. Recovery does not mean returning to a state identical to the original one, but to a state that responds to the same drivers and feedbacks. Resistance and recovery are therefore two sides of the resilience coin, and it is not clear how they covary, if at all.

The dual nature of resilience, developed in the general ecological literature, has for some reason not always been fully embraced by coral reef scientists. In the coral reef world, the term resilience has become interchangeable with recovery. For example, Hoegh-Guldberg et al. (2007) defined resilience as "the rate at which an ecosystem returns to a particular state after a perturbation or disturbance." Similarly, Hughes et al. (2007) equate resilience with "the ability of coral reefs to absorb recurrent disturbances and rebuild coral-dominated systems." Several authors have recognized the importance of both resistance and recovery, but called the latter 'resilience' (West and Salm 2003; Knowlton and Jackson 2008). Here, we use the terminology that resilience is a two-part process of 'resistance,' the ability of a system to withstand disturbance, and 'recovery,' the capacity of a system to bounce back to the original, pre-disturbance state.

Two important general issues surrounding resilience remain. The first is that resilience is not always a good thing. Resilience can be desirable or undesirable (Carpenter et al. 2001), depending on whether it characterizes ecosystem states that are or are not favored by society. Some ecosystem states, such as grasslands converted to desert because of overgrazing, are undesirable because they provide reduced services, but they can be highly resilient to external shocks. The second, related to the first, is that resilience needs to be defined not only in terms of the ecosystem state (i.e., resilience of grassland or of desert; resilience of coral-rich reefs versus coral-poor reefs) but also in terms of the perturbation of interest. A particular ecosystem state may be highly resilient to one type of disturbance, but less so to another. In this chapter, we specifically consider the resilience of coral-rich reefs to climate change-induced coral bleaching.

4.21.4 The Conventional View of Coral Reef Resilience

For most coral reef scientists, the conventional view of resilience is that pristine, unstressed coral communities are highly resilient to climate change and coral bleaching, and that human impacts reduce the ability of coral reefs to withstand such impacts (Hughes et al. 2003; Hoegh-Guldberg et al. 2007; Hughes et al. 2010). This conventional view of cumulative impacts and resilience on coral reefs is illustrated in the simple conceptual model shown in Figure 2(a), which shows the relationship between ecosystem state and climate disturbance. Ecosystem state can be thought of in terms of coral cover or coral species diversity, with the implicit notion that a coral-rich state is more desirable, while climate disturbance can incorporate both changes in mean and increased variability of various climate metrics, such as temperature. The general trajectory of coral reef ecosystems under thermal stress is expected to be sigmoidal (Figure 2), with relatively little change in ecosystem state over low levels of climate disturbance, and a precipitous shift to an alternative state once a climate threshold, commonly referred to as the tipping point, is exceeded (Hughes et al. 2010). The magnitude of the threshold can be used as a proxy for the resistance aspect of resilience.

This model can easily be adapted to reflect the additional impact of non-climatic, local stressors on coral reef state, and how this modifies the response of coral reefs to climate disturbances. According to the conventional view of resilience, more pristine coral reefs (i.e., with a higher coral cover and species diversity) have a high resistance to climate change and will only cross the tipping point and shift into an alternative ecosystem state at high levels of climate disturbance (Figure 2(a)). However, as non-climatic, local impacts such as fishing or pollution degrade the original ecosystem and move the state of the ecosystem down the y-axis, the coral community moves from a pristine to a disturbed, and finally a very disturbed assemblage (see photos, Figure 2). In response, the tipping point shifts to the left, whereby already disturbed ecosystem are less resistant to climate disturbances.

The mechanisms underscoring the conventional view of resilience often implicate overfishing and nutrient pollution in the loss of coral resilience (or really, resistance) to thermal stress and subsequent bleaching (Bellwood et al. 2004; Knowlton and Jackson 2008). Overfishing of herbivorous grazing reef fishes and nutrient pollution from coastal runoff can lead to the proliferation of macroalgae, which can harbor harmful microbes and pathogens that can increase coral disease (Nugues et al. 2004; Dinsdale et al. 2008). Fishing can also damage and break corals (Mangi and Roberts 2006) and reduce the types of suitable coralline algae substrate available for the settlement and growth of juvenile corals (O'Leary et al. 2012). Impacted colonies have to spend energy on tissue and skeleton repair, which can limit their ability to withstand and recover from climate-related stresses, such as coral bleaching and ocean acidification (Knowlton and Jackson 2008; Anthony et al. 2009, 2011; Carilli et al. 2009).

If coral reef state varies in relation to climate disturbance as depicted in Figure 2(a), then two predictions arise. First, coral communities exposed to local or chronic disturbance should be more susceptible to coral bleaching following thermal stress than less degraded, 'pristine' communities. Second, the combined impacts of local disturbances and global climate change should be either additive or synergistic, but definitely not antagonistic. We now briefly evaluate the empirical evidence for each prediction.

4.21.4.1 Prediction 1: Are Disturbed Coral Reefs More Susceptible to Climate Change?

The conventional view of resilience assumes that disturbed coral communities are less resistant to climate change than more 'pristine' and undisturbed coral communities. The observation that thermally induced coral bleaching events are increasing in frequency and extent (McWilliams et al. 2005; Hoegh-Guldberg et al. 2007) on reefs that are globally degraded (Gardner et al. 2003; Bruno and Selig 2007) could be taken as supporting evidence for the assumption that degraded reefs are more susceptible to climate change. However, this

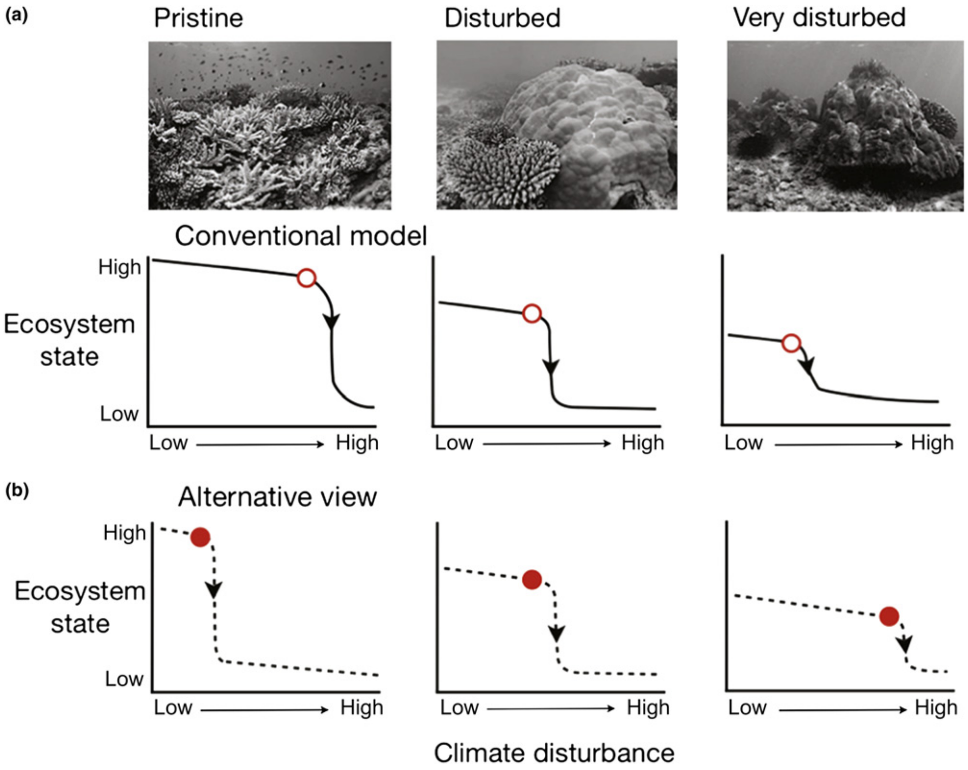

Figure 2 The relationship between ecosystem state and climate disturbance under conventional and alternative views of resilience. With the conventional view of resilience (a; solid lines), pristine, coral-rich reefs (left panel) are expected to tip into an alternative coral-poor state only at very high levels of climate disturbance. As coral reefs are increasingly degraded by chronic anthropogenic impacts (i.e., fishing, pollution; middle and right panels), the tipping points (open circles) are expected to shift to the left such that disturbed reefs are less resistant to climate disturbance than pristine reefs. In an alternative view of resilience (b; dashed lines), pristine coral reefs (left panel) are dominated by sensitive species, which have a limited resistance to climate disturbances, such as coral bleaching, which allows these reefs to tip very easily into an alternative coral-poor state. As human impacts remove these sensitive species from reefs (middle and left panels), the tipping points (solid circles) shift to the right, such that disturbed reefs may be more resistant to climate change. Photographs by Emily Darling.

signal is confounded by increasing sea surface temperature anomalies over time (Hoegh-Guldberg et al. 2007; Hoegh-Guldberg and Bruno 2010). Thus, even in the absence of degradation caused by local stressors, more widespread and/or intense bleaching would be expected if the response of corals is directly related to temperature.

There are arguably no pristine coral reefs left in the world. However, reefs around remote, uninhabited islands, such as the northern Line Islands in the Central Pacific, may be as close to pristine as any reefs on Earth (Knowlton and Jackson 2008). These reefs boast extraordinary densities of sharks and other large predatory fishes and high coral abundance (Sandin et al. 2008), which reflect the lack of local anthropogenic pressures which are pervasive elsewhere. These reefs should be highly resistant to high-temperature events. Yet, the corals of Palmyra, the best studied of the northern Line Islands, can bleach as severely as more impacted reefs (i.e., in American Samoa, Fiji, and the Philippines), despite the fact that they experience similar temperature regimes (Oliver and Palumbi 2009). We agree with Knowlton and Jackson (2008) who state “there are no data to suggest that corals become less vulnerable to bleaching with reduced local impacts.”

4.21.4.2 Prediction 2: Do Multiple Stressors Interact Additively or Synergistically on Coral Reefs?

The second assumption of the conventional view of resilience is that global climate change could reinforce the negative impacts of existing local stressors through additive or synergistic interactions. There have been few empirical studies of how multiple stressors interact on coral reefs. Until recently, most were small-scale experiments carried out in the laboratory, that involved only two stressors, and did not use the appropriate statistical techniques to reveal the interaction type unambiguously (Dunne 2010).

In one of the few attempts at unraveling the nature of interactions between local and climate stressors on natural reefs, Darling et al. (2010) evaluated the interaction between fishing and coral bleaching on coral cover using a long-term time series on Kenyan coral reefs. Not surprisingly, they found that both stressors influenced coral cover. A comparison of fished and unfished reefs, prior to the 1998 mass bleaching event, revealed that fishing on its own reduced coral cover by 51%, while a comparison of unfished reefs before and after the mass bleaching event suggested that the effect of bleaching was much larger, reducing coral cover by 74%. However, on reefs

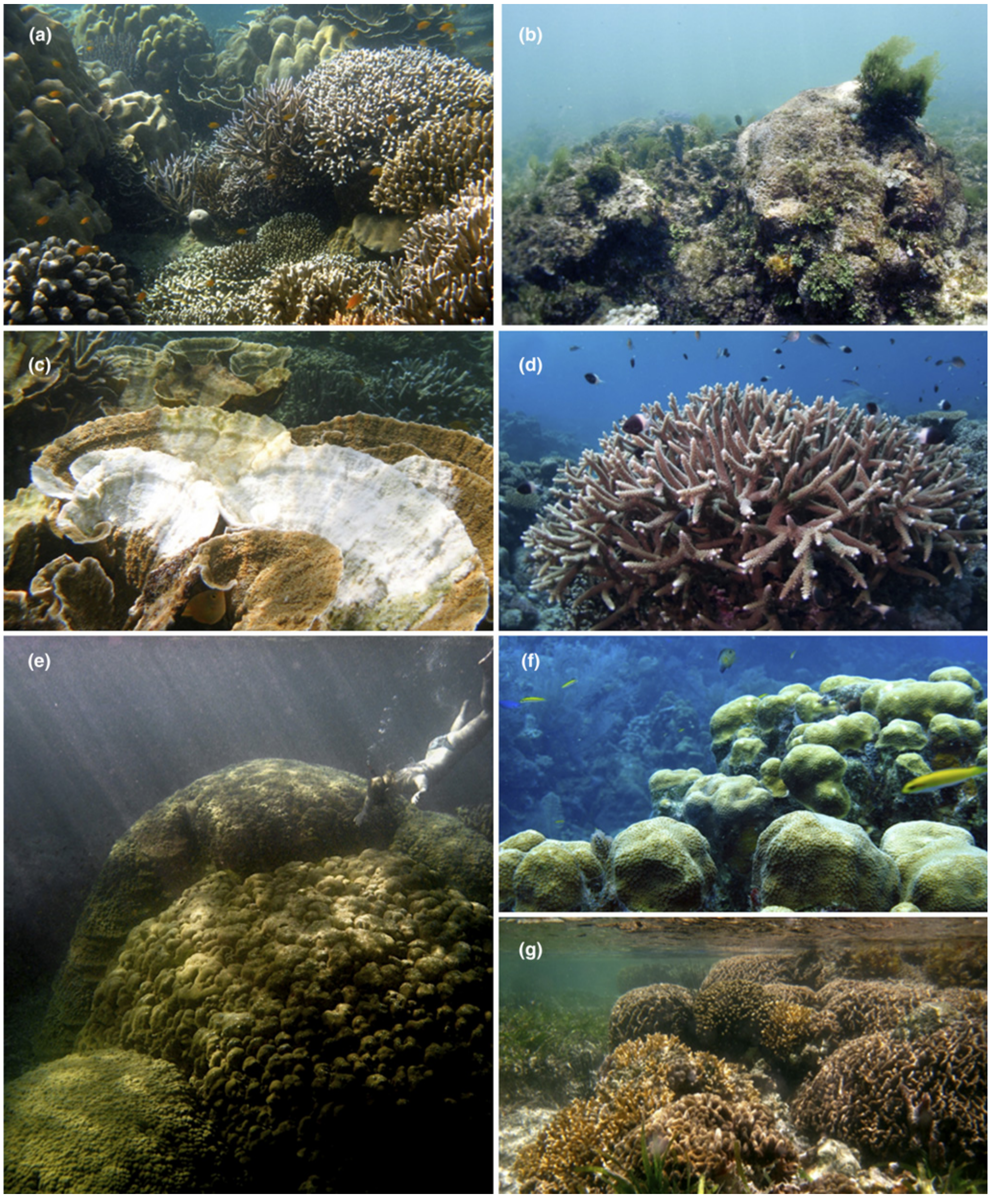

Figure 3 Examples of coral species with different responses to human disturbances and climate change. The type of coral community can determine whether a coral reef shifts from a coral-rich state (a) into a coral-poor state (b), immediately following climate disturbances, in particular coral bleaching. Stress-sensitive corals, such as species of plating *Montipora* (c) and branching *Acropora* (d), often occur on pristine and less disturbed coral-rich reefs, but are highly sensitive to thermal stress and coral bleaching. Large, slow-growing corals, such as species of *Montastraea* (e) and massive *Porites* (f), as well as small, fast-growing opportunistic and 'weedy' corals (g: Stylophora hystrix and branching Porites species) are often tolerant to human disturbances and also less affected over the long-term following bleaching. Photographs by Emily Darling.

subjected to both stressors (i.e., postbleaching, fished reefs), coral cover had declined by 72% on average, which was consistent with an antagonistic interaction, or a very weakly additive effect. This is not what the conventional view of coral reef resilience would have predicted.

4.21.5 An Alternative View of Resilience in a Disturbed World

There is an alternative view of ecological resilience to multiple stressors, which suggests that degraded reefs may, in fact, be more rather than less resistant to climate disturbances (Côté and Darling 2010). This alternative outlook is predicated on the fact that disturbance-sensitive taxa are lost following the impacts of local stressors, which can explain why more intact reef communities do not appear to be more resilient to climate disturbance. Local stressors can actually increase the relative abundance of disturbance-tolerant species within a community (Rachello-Dolmen and Cleary 2007; McClanahan et al. 2007a, 2007b; Cleary et al. 2008), and thus, the ability of an ecosystem to resist the impacts of climate disturbance.

Species are not lost randomly following disturbances (Srivastava and Vellend 2005; Ives and Carpenter 2007; Bracken et al. 2008; Zavaleta et al. 2009). Instead, disturbed ecological communities tend to first lose species with stress-sensitive life histories. Community composition shifts as these stress-sensitive species are replaced with stress-tolerant and opportunistic species that rapidly colonize following a disturbance. Thus, the remaining community can be composed of 'survivor' stress-tolerant and weedy species, which can be expected to be as resistant, or even more resistant, to subsequent climate disturbances.

There is ample evidence that such community shifts are occurring on coral reefs (**Figure 3**). Changes in the structure and composition of coral communities have been observed in the aftermath of diverse natural and anthropogenic disturbances, such as hurricanes and storms (Hughes and Connell 1999; Bak et al. 2005; Madin et al. 2008), pollution (Rachello-Dolmen and Cleary 2007), sedimentation (McClanahan and Obura 1997; Aronson et al. 2004; Dikou and van Woesik 2006; Cleary et al. 2008; Jupiter et al. 2008), fishing (McClanahan 2008; Darling et al. 2010), disease (Aronson et al. 2004), and outbreaks of coral predators (i.e., crown-of-thorns sea stars, Pratchett et al. 2009). In the Indo-Pacific region, the immediate effects of disturbances can generally shift coral communities from assemblages of stress-sensitive branching and plating corals, such as species of *Acropora* and *Montipora*, toward altered assemblages of stress-tolerant massive corals such as species of massive *Porites*, and faviids, such as species of *Cyphastrea and Favia* (Loya et al. 2001; McClanahan et al. 2007a, 2007b; Rachello-Dolmen and Cleary 2007; Cleary et al. 2008). In the Caribbean, the primary reef-building corals *Acropora* and *Montastrea* species have been replaced by 'weedy' coral species that form small colonies, grow quickly, and are short-lived (Knowlton 2001; Precht and Miller 2006). For example, the relative abundance of 'weedy' *Porites astreoides* has increased significantly over the past four decades (Green et al. 2008) as coral cover has declined – a sign of reef degradation – across the region (Gardner et al. 2003). Disturbed Caribbean reefs have also been shown to converge to communities dominated by *Agaricia*, whose opportunistic life history and high environmental tolerance have been suggested to explain its persistence on degraded reef habitats (Aronson et al. 2004).

The shift from stress-sensitive to stress-tolerant corals may make communities on disturbed reefs actually more resistant to bleaching and climate change. This alternative view of reef resilience is depicted in **Figure 2(b)**. Pristine or undisturbed communities are often dominated by disturbance-sensitive species that have limited resistance to climate stress and can tip into an alternative state at low levels of climate disturbance. When pristine reefs are exposed to the impacts of local stressors, their coral communities are altered toward a higher relative abundance of disturbance-tolerant species. Thus, degradation can shift the tipping point in response to climate change to the right, resulting in disturbed ecosystems having a higher resistance to climate disturbance than pristine, unstressed reefs. This alternative view of resilience will depend on whether a species' tolerance to a non-climatic disturbance is correlated with its tolerance to climatic impacts (i.e., positive cotolerance, Vinebrooke et al. 2004). Currently, there has been no evaluation of cotolerance in corals, although the patterns of species replacement within coral communities described above provide anecdotal evidence that cotolerance exists and that it may generally be positive (Côté and Darling 2010).

The resistance of coral communities to climate change will likely be a dynamic process as coral species adapt and acclimatize to thermal stress. Such adaptation can occur if corals acquire heat-tolerant symbiotic zooxanthellae (Berkelmans and Van Oppen 2006) or through the adaptation of host coral populations. For example, coral communities in South East Asia that bleached severely during the 1998 mass bleaching event were less impacted by a second bleaching event in 2010; both bleaching events were triggered by comparable temperature anomalies (Guest et al. 2012). What is remarkable is that some bleaching-sensitive corals, such as species of *Acropora* and *Pocillopora*, displayed more resistance to the successive bleaching event in 2010, possibly because of adaptation through natural selection – the loss of bleaching-susceptible individuals from the population in 1998 resulted in the survival and reproduction of bleaching-tolerant individuals that then increased the mean bleaching tolerance within the population in 2012 (Guest et al. 2012). It is unclear how generalizable these results are to other reefs and other coral species. Nonetheless, it provides some hope that even some of the most vulnerable corals would be able to increase their resistance to future thermal stress and coral bleaching events.

The alternative view of resilience focuses on some of the earliest changes in coral communities, the replacement of stress-sensitive corals with stress-tolerant and weedy corals. Such initial changes in ecological communities may increase the resistance of coral communities to climate change. However, species losses and declines, and patterns of community disassembly are not a single event, but a series of successive events that can reflect progressive and cascading losses in community and ecosystem function (Zavaleta et al. 2009). Even thermally tolerant species will have limits, which may be exceeded by future ocean warming and acidification (Hoegh-Guldberg et al. 2007). Overwhelming anthropogenic stressors may also precipitate the loss of even these hardy coral species and cause the replacement of coral communities with macroalgae, soft corals, seagrasses, and/or sponges (Norström et al. 2009). Furthermore, disturbed coral communities and alternative noncoral systems may be unable to support the immense biodiversity and economic benefits provided by intact coral reef ecosystems. A critical goal for coral reef conservation is therefore preserving coral populations and the reef architecture that supports reef-associated organisms and services, but how to do this will depend on how resilience to the cumulative impacts of local stressors and climate change actually works.

4.21.6 Implications for Conservation and Management

Increasing the resilience of coral reefs to climate change is a critical challenge for conservation and management. Local stressors are expected to erode the ability of coral reefs to withstand variations and longer-term change in climate conditions, particularly rising SSTs that provoke coral bleaching (Hughes et al. 2003, 2010; Knowlton and Jackson 2008). It is perhaps not surprising then that removing local stressors to increase resilience to climate change has emerged as a strong focus of coral reef management, perhaps more so than for any other ecosystem.

The conventional view of resilience suggests that removing local stressors and reducing human impacts should increase the ability of coral reefs to withstand climate change. As ecosystems are degraded by anthropogenic stressors, from pristine to disturbed, to very disturbed states, management that seeks to control local stressors and reverse degradation is therefore expected to increase resistance by shifting the tipping point back to the right and keeping reefs further away from such thresholds (**Figure 2(a)**).

One of the most popular ways that has been suggested to increase resilience to climate change is through the use of marine reserves, or MPAs (Hughes et al. 2003, 2010; Bellwood et al. 2004; Mora et al. 2006; Hoegh-Guldberg et al. 2007). MPAs are a form of spatial management that seek to control local stressors, primarily fishing. Integrated land and sea conservation efforts that target terrestrial activities adjacent to MPAs may also reduce coastal runoff and the amount of nutrient and sediment pollution that reaches coral reefs, but these are still relatively uncommon.

MPAs have been shown to have positive effects on the abundance and diversity of a variety of fish and invertebrates within their boundaries (Halpern 2003). Many reserves, but not all, have increased coral cover (McClanahan 2008; Selig and Bruno 2010; Darling et al. 2010), coral species diversity (McClanahan 2008), and coral recruitment (Mumby et al. 2007), with concomitant declines in macroalgal cover (Mumby et al. 2007; Mumby and Harborne 2010). Such benefits provided to coral communities are an indirect result of protecting fish populations from fisheries. In particular, the protection and recovery of populations of herbivorous fishes (i.e., parrotfishes and surgeonfishes) can maintain a variety of critical ecosystem functions, such as bioerosion, which exposes the reef matrix for coralline algae and juvenile corals, scraping, and grazing, which removes algae, leading to higher coral cover and coral recruitment (Elmqvist et al. 2003, Bellwood et al. 2004; Mumby et al. 2007). Healthy populations of herbivorous reef fishes can reinforce positive feedbacks that promote coral recruitment and healthy coral cover within MPAs, while the loss of herbivores can keep reefs in a coral-poor and unhealthy state (Mumby and Steneck 2008). Higher species and functional diversity on protected reefs can provide ecological insurance and functional redundancy, both of which are expected to increase resilience to climate disturbances, such as coral bleaching events (Loreau et al. 2003; Nyström et al. 2008).

However, any positive effects of MPAs on the resilience of corals to climate change may be unintentional. MPAs were designed to target local-scale impacts of anthropogenic stressors not the global-scale impacts of climate change (Hughes et al. 2010). There is no evidence that marine reserves are located in areas that are at less risk for thermal stress and coral bleaching (Maina et al. 2008), nor is there any expectation that marine reserves could alleviate the impacts of ocean acidification on corals (Mumby and Steneck 2008). Thus, it is probably not surprising that marine reserves do not reduce the frequency or intensity of thermally induced coral bleaching (Hughes et al. 2003; Coelho and Manfrino 2007; Mumby and Steneck 2008), or bleaching-induced coral mortality (Graham et al. 2008; Darling et al. 2010; Selig et al. 2012). It is sobering that the impacts of extreme events (i.e., anomalously high SSTs) can, in a single bleaching event, override years of coral recovery within MPAs (Darling et al. 2010; Selig and Bruno 2010).

Why are corals within MPAs not protected from coral bleaching? Why do they in fact often experience greater mortality following bleaching than corals on unprotected reefs (Graham et al. 2008; Darling et al. 2010)? The vulnerability of protected corals to thermal stress and bleaching could reflect the higher initial coral cover within MPAs; when disturbance strikes, there is simply more coral to lose (Graham et al. 2008, 2011a, 2011b). However, this is unlikely to be the whole story. The types of corals fostered by MPAs are often very sensitive to disturbance, and thus, it may not be only about how much coral can be lost, but how easily it can be lost (Darling et al. 2010). Notably, there is often a higher abundance of thermally sensitive corals, such as species of *Acropora* and *Montipora*, within marine reserves, leading to increased susceptibility of protected coral assemblages to climate disturbances (McClanahan et al. 2007a, 2007b; Darling et al. 2010). These differences in the types of corals and coral assemblages between protected and unprotected reefs could be due to an initial bias in site selection, whereby less degraded coral reefs with higher diversity of coral species are favored as sites where MPAs are established (Darling et al. 2010; Selig and Bruno 2010). There are few old and effectively enforced MPAs with pre-protection baseline data to evaluate the potential effects of site bias. However, in Kenya where data do exist for one MPA prior to protection, Darling et al. (2010) found that there was no difference in coral cover between the incipient MPA and fished reefs surveyed in the same year, suggesting that the effects of protection on resilience, at least in some MPAs, can be independent of bias associated with habitat selection. At such sites, protection itself, by eliminating destructive fishing and restoring fish populations, may favor the ecological succession of competitively dominant branching and plating corals that may be extremely sensitive to thermal stress and bleaching mortality.

The observation that coral assemblages within MPAs are disproportionately vulnerable to coral bleaching and climate change is consistent with the alternative view of resilience, which holds that managing local stressors in order to return ecosystems to a more pristine state may actually increase their vulnerability to climate disturbances. Thus, the effect of management action that seeks to control local anthropogenic disturbances and move communities back from a disturbed to a pristine state may inadvertently shift the tipping point back to the left by recovering pristine assemblages of disturbance-sensitive species (**Figure 2(b)**). The ultimate result may be to compromise the resistance of protected reefs to climate disturbances.

The cynical interpretation of the alternative view of resilience is that if degraded reefs are likely to weather the impacts of climate change, then we should allow degradation by local stressors to proceed. This would be extremely short sighted and the alternative view of resilience certainly does not advocate against the value of MPAs. MPAs provide diverse and unparalleled benefits to biodiversity and ecosystem function on coral reefs. The alternative view of resilience is instead a call to action for local management actions that are climate-smart.

4.21.6.1 Three Ways to Manage Coral Reefs in the Face of Climate Change

What are the options for managing coral reefs in the face of climate change if the alternative view of resilience applies? In other words, how can management increase the resistance of coral reefs to climate change if the conventional approach of controlling local stressors is not effective? One explanation for why MPAs have not buffered coral reefs from climate change disturbances, such as mass coral bleaching, is because of the current way they are designed (Selig et al. 2012). We can suggest three strategic ways that might help management to mitigate the risk from ocean warming and subsequent bleaching on coral reefs.

First, the placement of MPAs should be strategic with respect to where the greatest threat of future warming and thermal stress exists. The location of MPAs is too often the result of socio-political compromises and too seldom based on scientific advice. Spatial planning must take into account the fact that warming climate varies heterogeneously across the seascape. Not all areas of the world's oceans are warming equally, nor are they expected to in the future (i.e., Maina et al. 2011) and yet few MPAs are designed to take advantage of naturally cool conditions that can avoid the worst impacts of coral bleaching. For example, only 2 out of 61 managed coral reefs in the Western Indian Ocean are located in areas of low climate susceptibility (Maina et al. 2008). Finding and predicting 'cold spots' where MPAs will experience less thermal stress is critical for the survival of coral biodiversity. Some areas, such as the northwest Caribbean, and northern Madagascar and southern Tanzania in the western Indian Ocean appear to be exposed to low levels of climate stress (McClanahan et al. 2007a, 2007b; Maina et al. 2011). It is therefore imperative to target these climate 'cold spots' for protection (West and Salm 2003; Mumby and Steneck 2008). This will be difficult because it means that MPAs planning at the national scale may no longer be relevant. Instead, regional, transboundary coordination will be needed to identify priority areas and effectively protect them. Moreover, countries near 'cold spots' may have to bear the opportunity costs associated with MPAs establishment, such as the loss of fishing grounds, to generate conservation benefits at the regional scale. These inequalities may call for a reassessment in the way MPAs are funded in order to shift the financial burden from national to regional pockets (i.e., Balmford et al. 2004).

Second, MPA design must become adaptive. By this, we mean that the size, shape, and location of MPAs can be changed in response to new information. Flexible boundaries would allow MPAs to track the changing regimes and impacts of thermal stress and climate change (Maina et al. 2011). Corals have one of the fastest rates of poleward range expansion in response to climate change and range shifts have been observed to be as fast as 14 km year^{-1} (Yamano et al. 2011). Moving-target MPAs could therefore be used to protect novel coral assemblages, as their range limits expand or contract with climate change (Hobday 2011). MPA networks may also facilitate the maintenance of connectivity even with the impacts of climate change (Mumby et al. 2010; McLeod et al. 2009). It is widely held that MPAs work best when embedded in a web of protected areas, which are interconnected to various degrees by the exchange of nutrients, eggs, juvenile, and adult organisms that disperse with currents or actively migrate (WCPA/IUCN 2007). Patterns of connectivity are very likely to be affected by the regional and local impacts of climate change, which can alter currents and accelerate temperature-dependent processes such as larval development (O'Connor et al. 2007). However, actually implementing climate-tracking MPAs would require a major overhaul of the legislative process leading to MPAs designation, which in most places moves at glacial speeds.

Third, bigger may be better when it comes to MPAs. There is strong enthusiasm for the establishment of 'mega-MPAs' (i.e., Knowlton and Jackson 2008; Sheppard et al. 2012). Some recently established MPAs in the Pacific and Indian Oceans are very large indeed. The Chagos Archipelago, for example, is the world's largest MPA and covers more than 550 000 km^2, which is larger than France or the state of California (Sheppard et al. 2012). Large MPAs can provide important baselines for what nearly intact coral reef systems look like and how they function (Knowlton and Jackson 2008). However, it is unclear whether such 'pristine' baselines will be informative for understanding the dynamics of degraded reefs or if it is even possible to return severely degraded reefs to a state approaching these gold standards. Nevertheless, the main advantage of very large MPAs in terms of bolstering resistance to climate change is that not all reefs within them may be affected by acute climatic disturbances. Owing to their sheer size, mega-MPAs may well encompass climatic 'cold spots' provided by upwelling and other local oceanographic conditions (i.e., West and Salm 2003). Also, given the average size of most thermal anomalies, it is more likely that some areas within very large MPAs would escape thermal stress and bleaching anomalies (Selig et al. 2012). If large MPAs can provide a bleaching refuge to coral populations, this may give corals a chance to adapt through the natural selection of thermally tolerant symbionts and coral hosts (Berkelmans and Van Oppen 2006; Guest et al. 2012). Finally, large MPAs will also hold, in absolute terms, larger populations of stress-resistant corals than smaller MPAs.

4.21.6.2 Managing for Resistance versus Recovery

Even if protection does not usually enhance reef resistance to climate change, protection may provide substantial benefits for other facet of resilience: recovery. Many ecosystems have the capacity to recover from catastrophic disturbances. Large and infrequent pulse disturbances are the 'usual state of affairs' and in the past, they did not override the eventual recovery of ecosystems (Paine et al. 1998). For example, historical cyclones occur every decade or so on reef crests of the Great Barrier Reef and are considered 'normal' events that, until recently, did not provoke shifts to an alternative and undesirable macroalgal-dominated state (Hughes et al. 2010). This is likely because historical reefs were in a more pristine condition and able to bounce back following even large-scale natural disturbances. However, there is grave concern (and some empirical evidence) that the increasing scale of anthropogenic stressors is limiting the ability of ecosystems to recover from natural cycles of disturbance. For example, coral reefs along the Mesoamerican Barrier Reef in Belize and Honduras that had experienced more anthropogenic stress recovered more slowly, in terms of coral growth rates, from the 1998 bleaching event than less impacted reefs (Carilli et al.

2009). Similarly, the pristine and isolated reefs of Kingman and Palmyra in the Line Islands had higher rates of recovery following warm water and coral bleaching events than the more disturbed coral reefs of nearby Kiritimati and Tabuaeran, which are inhabited by people (Sandin et al. 2008).

MPAs are expected to increase coral recovery by maintaining the diversity of reef fish species and functional groups, particularly herbivorous fishes that graze algae and facilitate the recruitment of juveniles corals (Bellwood et al. 2004; Mumby et al. 2007; Hughes et al. 2010). The evidence for coral recovery following bleaching events within MPAs is still equivocal, but hopeful. Studies of reefs in the Bahamas (Mumby and Harborne 2010) and Indian Ocean (Ateweberhan et al. 2011) have found greater rates of recovery of live coral cover within MPAs than on unprotected reefs. However, studies of MPAs from around the world (Selig and Bruno 2010) and MPAs within Kenya (McClanahan 2008; Darling et al. 2010), and the western Indian Ocean (Graham et al. 2008) have found no evidence of higher recovery rates of coral cover within MPAs, and in some cases, coral recovery can be significantly slower in MPAs than on unprotected reefs (Graham et al. 2011a, 2011b). MPAs, especially older ones, can nevertheless be effective at preventing further coral losses that are occurring on more disturbed reefs, although any benefit of this protection can be wiped out following bleaching (Selig and Bruno 2010, Selig et al. 2012). Overall, the effects of MPAs on coral recovery are strongly context-dependent and differ across regions, the type of disturbance and the amount of postdisturbance coral cover (Graham et al. 2011a, 2011b). The species composition of the remaining coral community can also affect recovery as fast-growing, opportunistic genotypes or species will recover more quickly than slower-growing corals (Selig and Bruno 2010). It would be interesting in this context to see whether the fast-growing taxa that promote reef recovery are robust or sensitive to climate disturbances.

When considering the increasingly stressful future for most ecosystems, it is imperative to clearly understand the cumulative impacts of multiple stressors, as well define and distinguish between the two processes of resilience: ‘resistance’ and ‘recovery.’ While the main focus of management has been on recovery, finding ways to bolster resistance may be as important, if not more important, in the years ahead. For example, future projections of climate change predict that bleaching-inducing thermal anomalies will become more frequent (Hoegh-Guldberg et al. 2007; Donner 2009), which, if correct, would shrink the available window of coral recovery in between bleaching events. Perhaps this window is already too small, as many coral reefs have failed to recover even after more than a decade following the 1998 worldwide mass coral bleaching event (Graham et al. 2011a, 2011b). Furthermore, it is unclear if there will be any potential for recovery to chronic climate stressors, such as increasing average SSTs and the rising acidity of the world’s oceans.

Conclusions

The cumulative impacts of climate change and local human impacts of overfishing and pollution threaten the diversity, ecological function, and ecosystem services provided by coral reefs to millions of people around the world. Such ongoing and unprecedented changes, particularly the two faces of climate change – ocean warming and acidification – are creating a ‘brave new ocean’ with wide-reaching ecological consequences (Jackson 2008). Finding workable solutions is not easy and it is important to remember that any successful conservation initiative will require the support of local communities. The best opportunities for success may be to try many different tactics of conservation and management in order to hedge our bets as we identify a portfolio of actions that will have the most success at maintaining the ecological and socioeconomic services of marine ecosystems.

Strategic local conservation and management actions will hopefully buy us some time for globally supported initiatives to limit the human drivers of climate change. MPAs, and other forms of local land and sea management, are important tools to manage coral reefs, but they will need to be climate-ready and climate-smart. Coral reefs have a fighting chance if MPAs can protect large areas of critical habitat and are placed in areas of the ocean that are more likely to escape the full force of climate change. Identifying climate-resistant species and locations that are able to survive climate change will be equally important, as we expand our focus of resilience-based management to include both resistance and recovery. However, local conservation and management actions will likely never be the silver bullet that can single-handedly protect ecosystems against the risk from current and future climate conditions, particularly the unparalleled threat of ocean acidification.

The continuing degradation of coral reefs from climate change and other human impacts is an invaluable warning for other ecosystems around the world. Coral reefs are likely to be one of the first ecosystems to reach a tipping point of cumulative impacts. Understanding, quantifying and managing for multiple stressors on coral reefs can provide a benchmark for other ecosystems. Ecosystem-based management actions and policies that explicitly consider, evaluate, and adapt for interactions between stressors are immediately needed. We believe there is hope for the future of coral reef ecosystems and the millions of people who depend on the resources provided by coral reefs every day. However, in addition to managing local impacts, it is critical that we tackle the root anthropogenic causes of climate change in order to guarantee that future generations can benefit from the “surpassing beauty … and wonders of a coral sea” (Wallace 1869).

Glossary

Autotrophic organisms Photosynthesize (or chemosynthesize) to produce organic carbon, releasing oxygen; in an autotrophic estuary, oxygen production from photosynthesis and chemosynthesis exceeds consumption by respiration.

Barrage Is an artificial obstruction in a river designed to increase its depth or to divert its flow.

Benthic organisms (*benthos*) Live on or in the bottom sediments.

Diadromous fish Have some life stages in freshwater and some in saltwater. This includes *anadromous* species such as salmon which spawn in freshwater but spend much of their lives in saltwater, and *catadromous* species such as blue crabs that spawn in estuaries and rear in the ocean.

Epibenthic organisms Live on or near the bottom but may move up into the overlying water.

Epiphytic organisms Are algae and other small organisms that live on plant stems and leaves.

Eutrophication An increase in the rate of organic matter supply to an ecosystem, often to the point of undesirable consequences such as hypoxia.

http://dx.doi.org/10.1016/B978-0-12-384703-4.00438-X

Heterotrophic organisms Oxidize organic matter to obtain energy. An estuary that is net heterotrophic has a negative oxygen balance, consuming oxygen and organic matter and releasing CO_2.

Hypoxia Condition of low oxygen concentration (usually <2 mg l^{-1}) in natural waters.

Loading The rate at which a substance is brought into a water body, e.g., from a river.

Pelagic organisms Live in the open water, dissociated from the bottom or the shores.

Phenology The timing of natural events such as metamorphosis or migration.

Plankton Pelagic organisms with weak swimming ability. Most are small. This includes jellyfish and larval forms of most fish and benthic organisms.

Nekton Pelagic organisms with strong swimming ability, including nonlarval fish.

Residence time The average time that a molecule of water or a particle remains in a water body.

Stratification A vertical density gradient in which low-density water overlies higher-density water.

4.22.1 Introduction

As transition zones, estuaries are subject to influences from ocean, atmosphere, and land. Coastal and estuarine ecosystems are particularly sensitive to aspects of climate change, including rising sea level, increasing air temperature, and changing patterns of freshwater runoff (Goberville et al. 2010).

In places where human populations congregate, estuaries provide numerous valuable ecosystem services (Table 1). Estuaries play an essential role in buffering against storms, floods, and drought and in storing and processing nutrients, sediments, contaminants, and other materials. They provide habitat for countless species, including nursery grounds for some marine and anadromous species and feeding grounds for resident and migratory birds, and they support substantial commercial and recreational fisheries for both finfish and shellfish. Estuaries also provide opportunities for recreation and cultural activities. The value of estuaries as public resources is acknowledged by the establishment of reserves such as the US National Estuarine Research Reserve system, and governmental and nongovernmental bodies tasked with stewardship of estuaries.

Estuaries have been severely altered by human activities. Many cities and most ports and harbors are on estuaries. Shorelines have been realigned, and marshes and shoals filled and converted to hard structures such as airports, roads, and residential and industrial areas. The watersheds of estuaries supply water to farms and cities, altering seasonal patterns and quantities of freshwater flow. Rivers and estuaries serve as dumping grounds for waste. Contaminants, including heavy metals, organic toxins, nutrients, and pathogens, are discharged into estuaries. Some estuarine functions have been transformed by introduced species. As a result, many estuaries today would be unrecognizable to an observer of a century ago.

Three themes run through this analysis. First, climate is not the only driver of long-term change. The typical timescale for considering climate effects is up to the middle or the end of the twenty-first century. Over that timescale impacts of human activities in estuaries and their watersheds will intensify. Thus any effect of climate, including changes in regional and local climate, on estuaries can be understood only in the context of regional and local human activities including adaptation to climate effects.

The second theme is the heterogeneity among estuaries. The word 'estuary' is used to describe a diversity of water bodies ranging from coastal wetlands to inland seas, and from fjords to river deltas. They include the mouths of large rivers and isolated basins with no freshwater flow. Some are remote and nearly pristine, whereas others have been altered intensively for human use. Comprehending the scope of long-term change in estuaries as a general class of ecosystems requires careful attention to the unique characteristics of each estuary, and to the ways that climate and local influences will be modified by those characteristics (Canuel et al. 2012).

The third theme is the complex interactions among drivers and mechanisms of long-term change. Responses of estuarine ecosystems are unlikely to be related simply to the proximate influences of climate such as increased temperature.

We start with a discussion of the structure and ecosystem functions of estuaries and how they respond to physical, chemical, and biological influences (see Section 4.22.2), before turning to the important drivers of long-term change (see Section 4.22.3). We then examine the complex responses of estuaries to long-term change and provide a few specific examples by reviewing recent literature for three disparate estuaries (see Section 4.22.4). In Section 4.22.5, we summarize the implications for ecosystems services and management.

4.22.2 What Is an Estuary?

Pritchard (1967) defined an estuary as "a semi-enclosed coastal body of water which has a free connection with the open sea and within which seawater is measurably diluted with freshwater derived from land drainage." This definition, based solely on the physical and geographic features of estuaries, has proved too narrow. For example, many water bodies lacking freshwater runoff behave like estuaries (Potter et al. 2011). Moreover, the regional setting and bathymetry of estuaries may be as important as the degree of dilution by freshwater in determining biological features such as species assemblages (Kimmerer 1991).

Several broader definitions and classifications have been developed (e.g., Engle et al. 2007; Dürr et al. 2011), although no attempt to define such a heterogeneous collection will suit all needs (Elliott and McLusky 2002). For the purposes of this chapter, an estuary is defined as a body of water that: (1) is coastal; (2) is geographically distinguished from the open coast; (3) is permanently or intermittently connected to the

Table 1 Ecosystem services for estuaries based on Costanza et al. (1997). Threats are trends in climate or human activities that negatively affect the provision of that ecosystem service in some estuaries. Mechanisms refer to figures and text in Section 4.22.4.2 (increased temperature, habitat alteration, and increased water demand and nutrient loading are threats to all services but are not listed here)

			Examples of threats		
Service	*Ecosystem functions*	*Examples*	*Climate*	*Human*	*Mechanisms*
Disturbance regulation	Capacitance, damping, integrity of ecosystem response to environmental fluctuations	Storm protection, flood control, drought recovery; habitat response mainly controlled by vegetation structure	Sea-level rise Extreme storms, wind Reduced precipitation	Altered sediment loading Introduced plant species	Sediment (**Figure 3**) Vegetated beds (**Figure 4**)
Nutrient cycling	Storage, cycling, processing, acquisition of nutrients	Nitrogen fixation, nutrient and other elemental cycles	Sea-level rise Reduced precipitation	Increased water demand	Sediment (**Figure 3**) Vegetated beds (**Figure 4**) Eutrophication (**Figure 5**)
Food production	Portion of primary production extractable as food	Production of fish, shellfish, and game by hunting, gathering, fishing, or aquaculture	Reduced precipitation Ocean acidification	Introduced species	Runoff (**Figure 2**) Eutrophication (**Figure 5**) Species (**Figure 6**)
Raw materials	Portion of primary production extractable as raw materials	Production of fuel and other raw materials by harvest or aquaculture	Sea-level rise Storms, wind Reduced precipitation	Overharvest	Runoff (**Figure 2**) Eutrophication (**Figure 5**)
Biological control	Trophic-dynamic regulations of populations	Keystone predator control of prey species, reduction of herbivory by top predators	Sea-level rise Reduced precipitation	Introduced species Altered sediment loading Increased water demand Overharvest	Runoff (**Figure 2**) Eutrophication (**Figure 5**) Species (**Figure 6**)
Habitat/ refugia	Habitat for resident and transient populations	Nurseries, habitat for migratory species, regional habitats for locally harvested species, or overwintering grounds	Sea-level rise Storms, wind Reduced precipitation	Introduced species Altered sediment loading	Runoff (**Figure 2**) Eutrophication (**Figure 5**) Species (**Figure 6**)
Recreation	Providing opportunities for recreational activities	Ecotourism, sport fishing, and other outdoor recreational activities		Introduced species Overharvest	Eutrophication (**Figure 5**) Species (**Figure 6**)
Cultural	Providing materials and opportunities for noncommercial uses	Esthetic, artistic, educational, spiritual, and scientific values of ecosystems		Introduced species Overharvest	Eutrophication (**Figure 5**) Species (**Figure 6**)

open sea; and, has at least one of the following characteristics: (a) seawater mixing with freshwater from a river or groundwater; (b) elevated salinity caused by evaporation; and (c) when the mouth is open, tidal exchange with the ocean.

This definition includes water bodies that range in size from tiny (~1 km^2) salt marshes on arid coasts of western North America, Australia, and Africa to the Baltic Sea (375 000 km^2). Although larger, river-dominated estuaries are permanently open to the sea, a vast number of small estuaries dotting the arid coasts of the world are seasonally or infrequently open to the sea and can be hypersaline (Largier et al. 1997). Freshwater flows into estuaries range from none at all in desert estuaries such as Shark Bay, Western Australia (Smith and Atkinson 1984) to the massive flows of the St. Lawrence, Mekong, and other large rivers. Tides can be minuscule and depend mainly on wind and atmospheric pressure, or they can be driven to a height of many meters by the gravitational effects of the sun and moon. Exchange with the ocean may be mediated mainly by tides or by density-driven circulation as in fjords (Cokelet and Stewart 1985).

Estuaries are often characterized by their high physical energy in the form of tidal currents, wind waves, and freshwater inputs (Nixon 1988). Freshwater inputs and tidal flow also strongly link estuaries to their watersheds, adjacent lands, and the coastal ocean. This linkage transports sediment and dissolved substances such as nutrients and contaminants as well as organisms. Estuaries share some characteristics with each of the linked systems, while retaining some unique characteristics of their own (Elliott and McLusky 2002), many of these related to the interactions of fresh and saltwater in a shallow tidal environment.

The physical complexity of estuarine systems leads to a diversity of habitat types ranging from terrestrial with an aquatic influence (salt and freshwater marshes) to tidally dominated pelagic and benthic habitats. The resulting mosaic can support a high diversity of organisms. In addition, estuaries are often highly productive ecosystems because of high inputs of physical energy from atmosphere, ocean, and land (Nixon 1988). These features often mean that estuarine responses to external influences can be quite strong and complex.

Knowledge of estuaries is based on a rather small subset of the world's estuaries, principally those in more developed countries. This is because research focuses on larger estuaries and those where human impacts have resulted in conflict over resources and services. For example, a search in the Web of Science reveals more than 1000 articles with San Francisco Bay in the title and only 52 with Humboldt Bay, a small estuary in a largely rural area of northern California. This disparity is due to their relative size and the struggle over water, habitat, and other resources in the watershed of San Francisco Bay, which has led to a need for better understanding. This selection bias colors the conclusions of this chapter.

4.22.2.1 Physical Responses of Estuaries to External Influences

The physical configuration and dynamics of an estuary are influenced directly by factors that mediate responses of estuaries to climate change. This discussion focuses mainly on the estuaries with appreciable freshwater flow and tidal currents. Low-flow estuaries are discussed in Section 4.22.2.1.4.

Location is the primary underlying factor that determines the characteristics of an estuary. Latitude constrains regional climate, including storms, precipitation, temperature, and ice cover. Topography of the watershed influences precipitation and runoff. Regional geology and runoff influence the shape and bathymetry of an estuary and the loading, chemical composition, and size distribution of land-derived sediments (Canuel et al. 2012). Orientation of the coast determines regional weather patterns and conditions in the adjacent ocean; for example, the temperate west coasts of all major continents are upwelling regions with moderate ocean temperatures, persistent sea breezes, coastal fog, and dry summer conditions on land. Geographic location (e.g., latitude, continent) determines regional climate and therefore limits the species that could potentially colonize an estuary.

4.22.2.1.1 Tides and Flow

Physical conditions in estuaries respond to the interplay among bathymetry and flows driven by tides, freshwater input, and density differences between fresh water and saltwater. Tidal height at the mouths of estuaries is driven by a combination of astronomical effects (gravitational pull of the moon and sun) and meteorological effects (atmospheric pressure gradients and wind setup). Astronomical tides in the open ocean can range from a few centimeters (much of the Arctic Ocean) to several meters (northeast Atlantic Ocean), but these tides can be greatly amplified or suppressed by interactions with the coast. The dimensions and shape of estuaries can also amplify tidal energy through resonance (e.g., the semidiurnal lunar component in the Bay of Fundy, Garrett 1972) or attenuate it through narrow or shallow choke points (Fernandes et al. 2004).

Tidal flows transport salt, other dissolved and particulate matter, and even plankton and small nekton. Although the principal motion of tidal currents is oscillatory, several mechanisms cause substances and organisms to mix between the ocean and the estuary, and between regions within the estuary. Because of tidal mixing, any property that has a higher (lower) concentration within the estuary than in the coastal ocean will be mixed out of (into) the estuary. This includes any neutrally buoyant, passively moving particles or organisms in the water. However, sediments and other negatively buoyant particles can be trapped in estuaries because they sink. The interaction of tidal flows with sediment deposition, erosion, and transport results in complex geomorphic features such as offshore sand bars, mudflats, and deep channels.

4.22.2.1.2 Freshwater, Salinity, and Mixing

In estuaries with substantial river input, freshwater flow is a dominant control on physical conditions. However, estuaries respond differently to variations in river flow, depending on bathymetry, tidal currents, and wind. River input sets up seaward net flow that carries sediment and other materials and organisms out of the estuary. Freshwater mixes with ocean water, producing a horizontal salinity gradient. Saline water penetrates some distance into the estuary except where extremely high flow moves the salinity gradient into the ocean (e.g., Amazon River plume; Lentz and Limeburner 1995).

Overall, the rate at which estuarine water is mixed or discharged into the ocean determines the minimum rates needed for physical, chemical, and biological processes to be sustained. An estuary with a very high proportional flushing rate and short residence time because of high river flow or strong tides will export much of the river-derived material to the ocean and behave physically as either an extension of the river (if flow is strong) or the ocean (if flow is negligible). Conversely, estuaries with long residence times will retain river-derived materials and chemical and biological processes will be much more under endogenous control.

The salinity gradient produces a tendency for stratification, with low-salinity water at the surface and denser, high-salinity water at the bottom. Although much of the world's ocean is stratified by temperature, salinity has a much stronger influence than temperature on stratification in most estuaries. The extent and frequency of stratification is a key feature of estuarine physics and is used to classify estuaries because of its important role in mixing and transporting substances and organisms (Hansen and Rattray 1966). Stratification is enhanced by high river flow and is suppressed by strong tidal currents and wind, which mix the water vertically. Deep estuaries and deep channels in estuaries tend to stratify more than do shallow estuaries and shoals. For example, fjords are usually permanently stratified (Cokelet and Stewart 1985), whereas shallow lagoons are usually well mixed vertically (e.g., Newton and Mudge 2003).

The degree of vertical mixing or stratification determines the extent of the horizontal salinity gradient and its response to changes in freshwater flow (Hansen and Rattray 1965, 1966; Monismith et al. 2002). In a shallow, narrow, well-mixed estuary (e.g., Hudson River estuary), the salinity gradient moves along the channel in response to both tides and freshwater flow. In deeper regions or deeper estuaries, stratification limits the extent of this movement (e.g., Delaware Bay).

Stratification produces a physical barrier to vertical mixing, isolating the surface from the bottom waters and allowing gravitational circulation, whereby the ebb currents are stronger at the surface and flood currents at the bottom. This is a key mechanism for landward transport of sediment and organisms that sink into the bottom water, concentrating them at the landward end of deep channels or the landward limit of salt penetration (Postma and Kalle 1955). The paradoxical result is that increasing freshwater flow reduces residence time for water but can increase that of sediment and some organisms.

4.22.2.1.3 Other Riverine Inputs: Sediment

River flow brings more than water to an estuary: It carries nutrients, sediment, organic matter, organisms, and in many estuaries, contaminants. Sediment concentration typically increases sharply with increasing river flow. Loading, the product of concentration and flow, is therefore much higher during floods than at other times. Loading of organic matter from land can be an important component of the estuarine carbon budget and is also tied to runoff (Canuel et al. 2012).

Sediment loading to estuaries nourishes geomorphic features such as sand bars, marshes, and mudflats, and also controls the supply of suspended sediment that turns many estuaries turbid. Sediment within an estuary is alternately deposited and resuspended by wind-driven and tidal currents, and mixing with and net flow into the ocean remove suspended sediment.

4.22.2.1.4 Low-Flow Estuaries

Many, and perhaps most, estuaries worldwide have little or no riverine input for at least part of the year, including those in arid regions (e.g., Western Australia, southern Africa, southern California, and Mexico; Largier et al. 1997). In the absence of freshwater flow, tides, wind, and density-driven flow because of the salinity gradient mix estuarine waters with the ocean. These estuaries can fluctuate markedly between states of low salinity during wet periods and hypersalinity during dry periods (Largier et al. 1997), especially if their mouths close during low runoff (Potter et al. 2011).

Estuaries without appreciable river flow may still have a salinity gradient due to groundwater input or net precipitation or evaporation (Largier et al. 1997). These gradients are often sufficient to induce stratification or two-layer circulation, although stratification caused by temperature differences can be important in the absence of a strong salinity gradient.

4.22.2.1.5 Ocean Conditions

Conditions in the coastal ocean can have a strong influence on estuaries through changes in both water level and composition. Along coasts without substantial tidal energy, circulation between estuaries and the ocean is driven by wind, river input, and density gradients. Depending on the orientation and topography around the estuary, coastal wind patterns can influence vertical mixing, horizontal transport, and wind waves (Geyer 1997; Feng and Li 2010). Storms can inundate river mouths and coastal lakes with saltwater, rearrange sediments including sand bars and barrier islands, and provide a significant source of sediment to marshes (Liu 2004; Turner et al. 2006). Estuaries adjacent to upwelling zones can gain much of their productivity from the import of oceanic nutrients and organic matter (Smith and Hollibaugh 1997).

4.22.2.1.6 Vegetated Beds

Most estuarine classifications rely on physical characteristics such as bathymetry, freshwater flow, and stratification (e.g., Hansen and Rattray 1966; Elliott and McLusky 2002; Hume et al. 2007). However, estuaries can be shaped by biological factors, particularly the development of reefs and vegetated beds. Reefs formed by corals, oysters, and other calcifying organisms can alter the shape of an estuary. Mangrove forests, marsh vegetation, and seagrasses alter flow patterns (Nepf and Vivoni 2000) and thereby trap and consolidate sediment. This modifies and stabilizes bathymetry, producing habitat for a variety of species and supporting or concentrating ecosystem processes (Waycott et al. 2009; Polidoro et al. 2010). Mangroves and marsh plants, occupying the land margins of estuaries, provide a valuable buffer against storms and can 'migrate' up or down the land gradient through die-back and growth as conditions change (Simas et al. 2001).

4.22.2.2 Biological Responses of Estuaries to Physical Conditions

Many estuaries support high biological productivity owing to their physical dynamics, shallow depths, and high inputs of nutrients (Nixon 1988). Biological interactions in estuaries can be strong (e.g., Nichols et al. 1990), though sometimes difficult to detect because of the physical variability. Temperature has a direct influence on biota, but most mechanisms by which climate and other external drivers affect estuarine biota are indirect, including residence time, the location of the salinity gradient, stratification, and transport of nutrients, other substances, and organisms from the river and the ocean.

Estuarine habitats can be divided into shallow vegetated beds including marshes, seagrass beds, and mangrove forests, and open-water habitats. Which habitat predominates depends on physical attributes of the estuary such as depth, residence time, sediment supply, tidal range, and freshwater flow. Although there are considerable interaction and movement between these habitats, vegetated beds are essentially terrestrial (although wet), whereas open-water habitats are truly aquatic. In vegetated habitats, space is a resource worth competing over, whereas in open-water habitats resources such as food and nutrients are ephemeral. The key organisms in vegetated beds (i.e., vascular plants that provide the structure) are long-lived and many have limited dispersal capabilities. In open waters, the key producers are microbes with lifetimes of hours to days, and dispersal is rapid even for most benthic organisms which have planktonic larvae. This discussion excludes coral reefs, which have characteristics of both of the preceding classes.

Estuarine species are most abundant over a particular range of salinity and less abundant where salinity deviates from that range. Plankton and nekton live in a moving frame of reference and therefore move with the salinity gradient. Benthic organisms and marsh vegetation may take weeks, months, or even years to adjust to a changed salinity distribution by dying back where conditions are unfavorable and colonizing favorable areas.

An estuary with short residence time caused by strong tidal mixing or high freshwater flow may support small plankton species only if they have very rapid population growth (Rogers 1940), although many estuarine animals have swimming patterns that overcome these losses (Cronin and Forward 1979). At intermediate rates of mixing, the abundance of phytoplankton may be directly related to residence time (Jassby et al. 2002). Increasing freshwater flow may stimulate phytoplankton production through increased nutrient loading (Nixon 1988; Mallin et al. 1993) or through enhanced stratification that traps phytoplankton in well-lit surface waters (Cloern 1984). By these mechanisms, phytoplankton production can either increase or decrease with freshwater flow, and these responses can occur in the same estuary. For example, in the San Francisco Estuary (SFE) phytoplankton biomass varies inversely with flow through residence time in the freshwater region (Jassby et al. 2002), positively with flow through stratification in South San Francisco Bay (Cloern 1984), and is unresponsive to flow in the low-salinity region of the northern estuary (Kimmerer et al. 2012).

Stratification not only stimulates phytoplankton growth, it also traps settling phytoplankton and other organic matter in the deep waters of an estuary, where microbial respiration can result in hypoxia, limiting the suitability of these areas for many organisms (Diaz 2001; Conley et al. 2009). When phytoplankton biomass is high and the estuary is eutrophic because of the combination of nutrient loading and stratification, the resulting turbidity can inhibit the growth of plants such as seagrasses through light limitation (Short and Neckles 1999). In some estuaries suspended sediments limit penetration of light into the water and thereby limit production of phytoplankton and rooted plants even when nutrient concentrations are high (Cole et al. 1992; Goosen et al. 1999).

The abundance of planktonic animals and small nekton may vary with freshwater flow because of changes in phytoplankton biomass. Abundance may increase with flow because stronger stratification causes higher retention of species that swim into deeper water or migrate in synchrony with tidal currents (Cronin and Forward 1979). Up-estuary transport of young crabs and shrimp could be enhanced, resulting in higher survival, when high freshwater flow causes increased landward flow of seawater near the bottom (Schlacher and Wooldridge 1994; Kimmerer 2002). Abundance may also vary with residence time as for phytoplankton. Transport of the young of anadromous species such as striped bass and salmon from the river to the estuary may be enhanced by high river flow (Stevens and Miller 1983).

4.22.2.3 Human Influences

Most of the world's coastal cities are on estuaries, and many estuaries have been heavily modified to support human activities (e.g., Nichols et al. 1986; Lotze 2010). Marshes (Day et al. 2008) and mangrove forests (Polidoro et al. 2010) have been destroyed for development, resulting in extensive losses of estuarine habitat as well as increasing risk of shoreline erosion. Shorelines have been modified further by the installation of docks, jetties, and hard barriers such as levees, seawalls, and tidal gates (Nienhuis and Smaal 1994). These physical alterations together with channel dredging and dredge disposal amend the response of an estuary to tides, freshwater flow, and storms.

Land use in the watershed can have substantial impacts on an estuary. Extensive agriculture and urban development demand freshwater, cause erosion, and increase peak flows during storms. Diversion of freshwater from the watershed and impoundment of water behind dams reduce the rate and dampen the seasonal pattern of freshwater flow into estuaries (Poff et al. 2007). In addition, rivers and estuaries can be starved of their sediment supply by trapping behind dams (Schoellhamer 2011).

Some of the freshwater diverted from watersheds and estuaries is lost to evapotranspiration and some returns as discharge from farms, wastewater treatment plants, and industrial facilities (or returns elsewhere as precipitation). Eutrophication from nutrients and organic matter in point-source (wastewater treatment plants) and non-point source (agricultural and urban runoff) discharge is the predominant cause of environmental degradation in many estuaries (Cloern 2001).

These human influences have numerous repercussions for estuarine biota, many of which are discussed in Section 4.22.4.2. In extreme cases, dams and diversions can starve estuaries of freshwater, resulting in a complete reorganization of ecosystems (e.g., Colorado River estuary; Kowalewski et al. 2000). Similarly, estuarine ecosystems can be severely degraded by extensive hypoxia, resulting in the loss of valuable species (Diaz 2001). The global movement of species through shipping (in ballast water or cargo or attached to ships) and other activities is homogenizing biota across oceans (Ruiz et al. 1999).

4.22.2.4 Ecosystem Functions and Services

A variety of ecosystem functions and services can be attributed to estuaries (Table 1). We take an inclusive view of ecosystem services beyond those that have a market value (Norgaard 2010).

Estuaries serve as corridors linking land to sea. They supply water, nutrients, and organic matter to the coastal ocean and supply sediment, including most of the sand that forms beaches in temperate zones. Estuaries and in particular their vegetated beds act as a filter, dampening variation in riverine and oceanic sources of materials and removing or burying contaminants (Klamer et al. 1994; Dürr et al. 2011).

Important nutrient cycling processes in estuaries can include nitrogen fixation (Howarth et al. 1988), denitrification (Seitzinger 1988), uptake, remineralization, and sequestration in plants and sediments. Some estuaries are net autotrophic in that they consume inorganic nutrients and CO_2, producing organic matter that is either buried or exported to the coastal ocean (Kemp et al. 1997); some are net heterotrophic (Smith and Hollibaugh 1997); whereas others are close to balance (Smith and Hollibaugh 2006).

Storage of materials within an estuary generally increases with residence time of the water and with the strength of trapping of sediments by estuarine currents. Growth of organisms resident in an estuary results in storage of some of this material in their biomass, with turnover times that can be much longer than that of the water. Sediments form another pool for nutrients, contaminants, and other substances with an even longer turnover time than that of most organisms. Sediments may become buried, sequestering these materials, or they may be exported to the coastal ocean during periods of tidal or storm-driven erosion.

Estuaries provide habitat for a variety of organisms, in particular nursery habitat for many marine and anadromous species. Most estuaries support potentially large populations of mollusks, crustaceans, and finfish, and many also support marine mammals and large populations of birds. Anadromous fish such as salmon and sturgeon use estuaries as rearing habitat and for passage to and from spawning grounds.

4.22.2.5 Estuaries as Islands

Some of the most severe effects of global warming have occurred on mountaintops where low-lying areas form a barrier to species' range extension and thereby isolate species' populations (Parmesan 2006). Mountaintops in this case are effectively islands with limited dispersal for these species. Estuaries may function as islands in that the coastal ocean may be inhospitable to some species because of high salinity, long distances between estuaries, or adverse current patterns. Genetic divergence among populations of copepods in estuaries along the Atlantic coast of North America (Caudill and Bucklin 2004; Milligan et al. 2011) and among populations of gobies in California estuaries (Earl et al. 2010) suggests limited dispersal among estuaries for these organisms. Other case studies indicate high connectivity, such as between estuarine populations of copepods in California and Mexico (Trujillo Ortiz et al. 1995) and amphipods in New Zealand (Stevens and Hogg 2004).

Resident species in isolated estuaries may be vulnerable to local extirpation. For example, populations of several diadromous fishes in the North Atlantic basin, including Atlantic salmon, have been extirpated from estuaries through a combination of climate and local anthropogenic effects (Limburg and Waldman 2009). No examples have been reported to date of extinction of estuarine species caused by climate change.

4.22.3 Long-Term Change

This section discusses direct effects of climate change and of other, mostly anthropogenic long-term changes. For each mechanism of long-term change, we assess the likely magnitude of the effects on estuaries to provide a means of comparing among these effects and assessing their relative importance. Although direct effects of both climate and human intervention have been observed and are forecasted to grow, indirect effects and interactions among these effects may be more important at the level of individual ecosystems, as discussed in Section 4.22.4 Modes of Estuarine Response.

4.22.3.1 Climate Change

Of the many ways that climate Change may influence estuaries, three are consistently present in model forecasts and observed in historical records and are likely to affect most estuaries (Table 2, Figure 1). Global mean air and ocean temperatures are predicted to continue rising, although with considerable variability, and some areas will even cool (e.g., upwelling zones). Sea-level rise is also global, but heterogeneous and modified locally by tides and weather. Ocean acidification is pervasive, although several processes may offset its effect in estuaries.

Other modes of global climate change are either more spatially and temporally sporadic than the preceding three, or their historical and forecasted trends are less certain (IPCC 2007). In particular, precipitation, storm intensity, and wind speeds will increase in some areas but not in others.

4.22.3.1.1 Temperature Increase

Temperature exerts a fundamental control on biochemical rates in ecosystems and on physiological rates in most marine and estuarine organisms. Biogeochemical rates such as nutrient cycling generally increase with temperature. Solubility of oxygen in water decreases as temperature rises, so that less microbial respiration is required to reach a hypoxic condition. At the same time, respiration increases with increasing temperature at a higher rate than does photosynthesis, so that microbial processes will consume more oxygen (Lopez-Urrutia et al. 2006). The overall effect is a trend toward net heterotrophy and an increased incidence of hypoxia in estuaries. Warming may also contribute to the formation of harmful algal blooms, which appear to be increasing in water bodies worldwide (Paerl and Huisman 2008).

Rates of processes such as respiration and consumption increase with temperature up to a point beyond which they fall off rapidly toward the upper lethal temperature (Pörtner 2002). The setpoints and temperature sensitivities vary among the physiological processes and with species and acclimatization history. Below the peak, rising temperature causes positive responses of consumption, nutrient uptake and release, reproduction, growth, and development, while at the same time mortality rates increase as predators, pathogens, and

Table 2 Projected long-term changes in estuaries relative to current conditions. Quantitative projections are in the middle of the range; see Section 4.22.3 for sources. Causes in bold are those with supporting evidence and consistent trend in many estuaries. Projections listed as "Regional" refer to increases in some areas and decreases in others; those listed as "Variable" have trends with less statistical support than, for example, temperature. Consequences exclude interactions among causes and effects (see Section 4.22.4.2 Interactions).

Cause	*Projection to 2100*	*Potential consequences for some estuaries*
Temperature rise	3 °C	Change in phenology, range of estuarine species Species introductions and extirpations Reduced survival, reproduction, and growth of desirable species
Sea level rise	1–2 m	Reduced growth rate of submerged vegetation Increased erosion of shorelines, mudflats, and marshes Increased inundation of shore Increased salt penetration, species changes Increased strength of tidal currents
Acidification	+0.3 pH units	Impaired calcification of bivalves
Total precipitation	Regional	Possible increase in extreme floods and droughts
Timing of runoff	Regional, earlier	Shift to earlier runoff peak where dominated by snowmelt
Wind speed	Variable	Increased erosion with increased wind speed; increased upwelling
Storm Intensity	Variable	Increased erosion, flooding
Catastrophic change		Breaches of levees or barrier islands due to storms may alter physical configuration Shifts to alternative stable ecosystem states
Dams in watershed	Increases in less developed areas	Reduction in total freshwater flow, alteration of seasonal hydrograph
Dredging/armoring	Regional increase	Increase in erosional power in unarmored areas, loss of sediment for marshes
Population growth	Regional increase	Increased demand for ecosystem services; increased urbanization
Water demand	Regional increase	Decreased inflow and increased salinity
Sediment loading	Regional decrease	Increased water clarity, erosion Increased loading with storm intensity, decreased water clarity, deposition
Habitat alteration	Regional increase	Elimination of vegetated areas, degradation of others
Nutrient & organic loading	More eutrophication	Hypoxic areas, harmful algal blooms
Harvest	Regional increase	Alteration of trophic structure
Species introductions		Difficult to predict; depends on what species and where

parasites increase their metabolic rates. Thus, the vital rates of birth and death for any population vary nonlinearly with temperature, and no two populations respond the same way. Sharp changes in relative abundance are likely because of these differential responses to temperature among the species in an estuarine assemblage.

Temperature also affects organisms directly through their phenology, and this effect could be significant for estuarine species, although there are few reports of phenological shifts from estuaries and coastal environments. Photoperiod has an equally strong influence on phenology, and as spring warming comes earlier and fall cooling later, various organisms may receive conflicting signals from temperature, season, and sunlight, and reproductive success may decrease (Lawrence and Soame 2004). For example, a delay in reproduction of autumn-spawning limpets because of higher temperature resulted in recruitment failures (Moore et al. 2011).

Increases in temperature at one location may result in extirpations but favor populations of species with higher thermal maxima. At a larger scale the net result is poleward movement in the ranges of species that can cross the intervening ocean. Such range shifts have been observed in open-ocean phytoplankton, zooplankton, and fish (Mantua et al. 1997; Reid et al. 1998; Beaugrand and Reid 2003; Perry et al. 2005). Range shifts in invertebrates of rocky shores in central California have been linked to increasing temperature (Sagarin et al. 1999). High-latitude estuaries and coasts will lose ice cover and the intense spring bloom of ice algae will give way to a more diffuse bloom of phytoplankton, cutting off much of the food supply to the benthos (Grebmeier et al. 2006).

Case studies in estuaries show some evidence of range shifts in response to warming. A northward shift in distributions of predatory marine species in response to decadal-scale climate fluctuations may have induced a trophic cascade in the SFE (Cloern et al. 2007). Encroachment of tropical species of fish into a South African estuary apparently was driven by increases in temperature (James et al. 2008). A similar pattern was observed in seagrass meadows of the northern Gulf of Mexico (Fodrie et al. 2010). However, no shifts were seen in invertebrates on rocky shores of eastern Australia over 50 years despite measurable warming (Poloczanska et al. 2011). A meta-analysis showed no clear evidence of range shifts in marine, estuarine, and freshwater fishes in Australia, although the authors of that study acknowledged the difficulty of determining ranges of such highly mobile species (Booth et al. 2011). The paucity of reports of range shifts in estuaries may reflect the paucity of studies or an actual lower rate of range contraction or expansion in estuaries compared to other ecosystems.

4.22.3.1.2 Sea-Level Rise

Global sea-level rise has been estimated to accelerate and to reach 1–2 m by 2100 (Vermeer and Rahmstorf 2009).

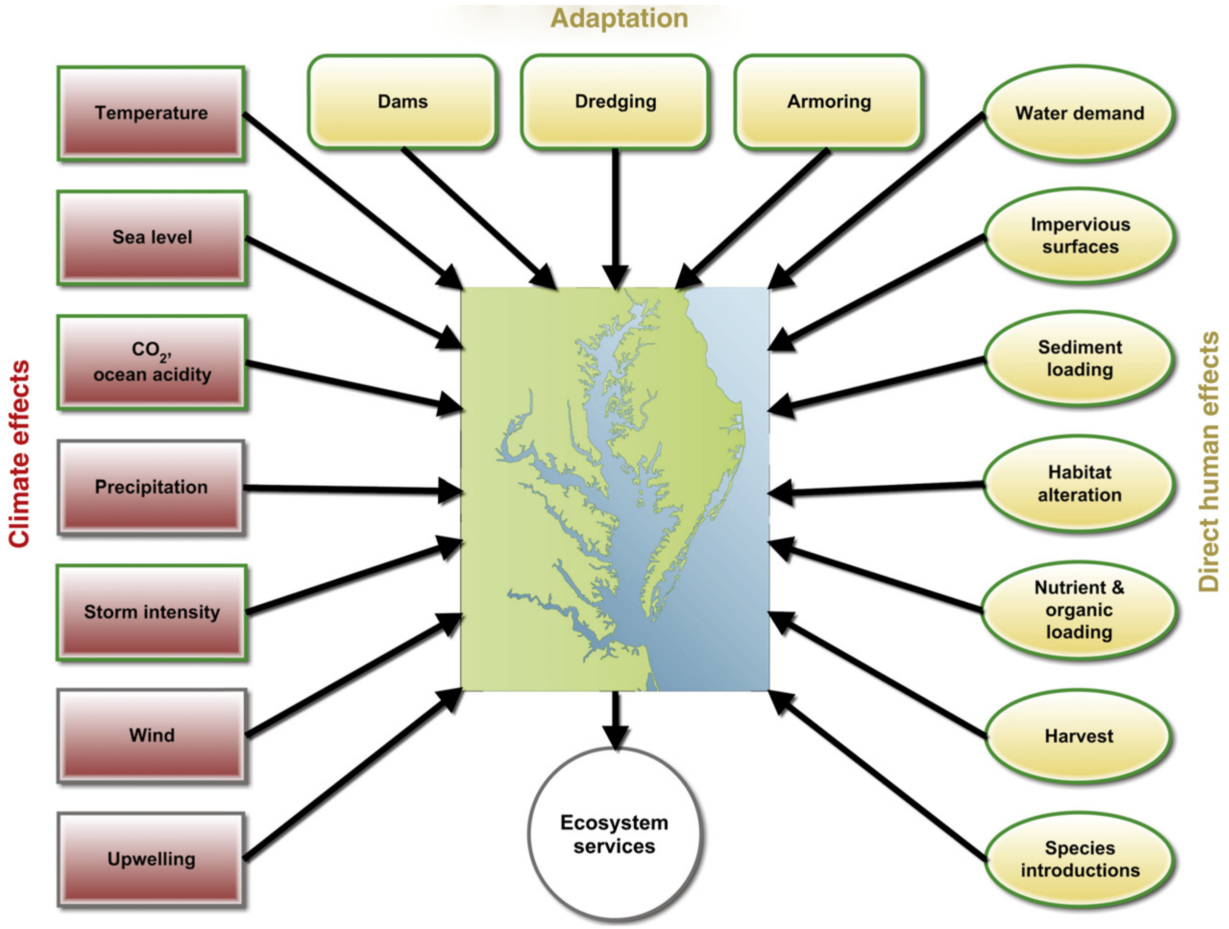

Figure 1 Schematic of significant long-term influences on a generic estuary, represented here by the Chesapeake Bay. Each box is a potential influence on estuarine functions or the provision of estuarine services. Rectangular boxes on the left-hand side are climate effects, ovals on the right-hand side are human activities, and rounded rectangles at the top are human adaptations to climate, and other long-term, changes. Green borders indicate a positive trend in some regions. Gray borders indicate a positive or negative trend. Black arrows indicate causative relationships between influences and ecosystem responses that may be positive or negative. Table 2 gives additional details about mechanisms underlying some of these relationships.

However, locally the rise is amplified or offset by erosion, accretion, or vertical movements of the earth's crust (Peltier 1999). For example, the Mississippi Delta is losing land area because of sea-level rise coupled with a reduction in sediment supply in the Mississippi River caused by dams. Rising relative sea level will have numerous direct effects and many indirect effects on estuaries. The most obvious effect would be inundation of lands that are now dry and conversion of intertidal habitats to subtidal. For example, the area inundated by the 100-year flood in San Francisco Bay at a 50-cm higher sea level would include about 35 000 ha of nearshore lands, of which about half is developed and half is grassland (Knowles 2010).

The consequences of sea-level rise are difficult to predict in a given estuary. First, high tides are likely to increase more than mean sea level through frictional effects, and this effect would be exacerbated by any increase in tidal resonance, storm surges, and freshwater floods (Cayan et al. 2008). Second, increasing sea level will alter sediment transport through erosion, deposition, and changes in circulation patterns, resulting in a change in bathymetry that is difficult to predict without accurate sediment-transport models. Third, trapping of sediment by vegetated areas such as marshes and seagrass beds and upslope migration of marshes and mangrove forests will alter the outcome of rising sea level. Finally, human populations will not remain passive to rising sea level, but will armor shorelines with levees and seawalls.

4.22.3.1.3 Acidification

Ocean water resists changes in pH through a buffering system in which dissolved CO_2 is in chemical equilibrium with hydrogen, bicarbonate, and carbonate ions. Since the beginning of the industrial age about 40% of the net release of CO_2 into the atmosphere has dissolved in the ocean (IPCC 2007). This increase in dissolved CO_2 has shifted the equilibrium to make the ocean more acidic by 0.1 pH, and projections are for a further reduction by 2100 of $\sim$0.3 pH units (Caldeira and Wickett 2003), a 2.5-fold increase in acidity.

The decrease in ocean pH will cause dissolution of, and increased metabolic cost of producing, hard parts of calcareous organisms including corals and bivalves. The most prominent effect is the reduction in calcification by corals, which can slow their growth and kill reefs (Orr et al. 2005). Oyster, clam, and mussel beds and several groups of open-ocean plankton are also likely to be affected severely and rather unpredictably. For example, two species of oyster that were exposed experimentally to different levels of atmospheric CO_2 had very different responses in growth and shell formation (Miller et al. 2009).

Research since the IPCC report (2007) reveals that a wide variety of organisms may suffer negative physiological effects from acidification (Fabry et al. 2008), although effects on noncalcifying organisms may not be severe (Hendriks et al. 2010). Ecological effects of acidification have scarcely been addressed.

The pH along coasts and in estuaries is subject to influences not prominent in the open ocean, notably inputs of wastewater, freshwater, sediment, acids, and bases, as well as local biological processes, particularly microbial production and respiration, that alter total CO_2 concentrations. Upwelled water is initially supersaturated with dissolved CO_2 and low in pH, although pH increases with time at the surface (Fassbender et al. 2011). Estuaries generally are sources of CO_2 to the atmosphere because of a combination of net heterotrophy, eutrophication, and discharges from wastewater treatment plants (Caffrey 2004; Borges et al. 2006; Feely et al. 2010; Cai et al. 2011).

4.22.3.1.4 Storms and Precipitation

The rising heat content of the oceans adds moisture and energy to the atmosphere and will increase the frequency or strength of storms (Knutson et al. 2010), but regional weather responses are rarely known. Nevertheless, future precipitation and the frequency and intensity of storms are less well constrained in global climate forecasts than are temperature, sea level, and acidification (Nijssen et al. 2001; Trenberth et al. 2003). Regional projections of annual precipitation using downscaled climate models differ even in the direction of the trend. The response of precipitation to ocean-scale climate forcing such as the El Niño-Southern Oscillation (ENSO) is informative: El Niño patterns bring wet conditions to northwestern North America and dry conditions to southern California and western Mexico, and central California can be either wet or dry (Cayan et al. 1999). Where much of the runoff comes from melting of snow or glaciers, the warming trend will lead to earlier runoff peaks. This is both observed and forecasted for wide areas of western North America where much of the annual runoff is from snow melting in high mountains (Aguado et al. 1992).

Violent storms can have a wide variety of physical effects on estuaries that depend on orientation of the coast, elevation, and vulnerability of coastal features to overtopping or scour. Infrequent, powerful storms may be important in supplying sediment to coastal marshes and beaches (Turner et al. 2006). Even in the absence of geomorphic effects, storms can cause flooding and temporary transformation of estuaries into freshwater systems, or coastal lakes into saline systems (Paerl et al. 2001; Liu 2004).

4.22.3.1.5 Wind and Upwelling

Atmospheric pressure gradients responsible for wind are likely to intensify with increasing temperature gradients and storm intensity. The direct influence of wind on estuarine dynamics depends on water depth and wind direction (see Section 4.22.2.1.5 Ocean Conditions.). On the West coasts of continents an increase in wind strength is likely to result in an increased frequency and intensity of upwelling (Snyder et al. 2003), potentially increasing the loading of nutrients and organic matter to estuaries.

4.22.3.2 Direct Human Effects

Human population is likely to continue growing, although at a declining rate (United Nations 2004). At least for some time in some countries this growth will be accompanied by increasing standards of living resulting in an increase in efficiency of agriculture and a shift in the economic basis from agriculture to industry. More people will live in cities and around estuaries. Increasing urbanization, together with increasing demand for water, land, and food, will increase demand for estuarine services and have negative impacts on estuaries (**Figure 1**, **Table 2**).

Globally, forecast shortages of water are more likely to arise from increasing demand as human populations grow than from decreasing precipitation (Vörösmarty et al. 2000). Current shortages in arid regions will be exacerbated. Major river systems that form or cross international borders include the Amazon, Nile, Mekong, Brahmaputra, and Tigris-Euphrates, many of which have substantial dams in place or under construction. Although minimum flows are legally mandated in many rivers and estuaries (e.g., SFE; Kimmerer 2002), such mandates are difficult to maintain where rivers cross borders, as in the Colorado River estuary (Kowalewski et al. 2000).

The increasing conversion of land to support the growing human population will result in more destruction of marshes and mangrove forests for farming, urban development, and biofuel (Polidoro et al. 2010). Some shifts in land use, such as intensification of agriculture, and limits on water supply are likely to lead to further increases in use of fertilizer and agricultural chemicals (Tilman et al. 2001). The resulting increase in nutrient loading to estuaries will worsen eutrophication (Nixon 1995; Tilman et al. 2001).

Sediment inputs to estuaries likely will be reduced in most areas of the world. Dams trap sediments, causing erosion in rivers downstream (Kondolf 1997) and limiting sediment supplies for maintaining estuarine marshes (Blum and Roberts 2009), with consequent erosion in estuaries as seen in the Nile and Mississippi Deltas. The reduction in sediment supplies to river-dominated estuaries will cause turbid waters to clear (Schoellhamer 2011), contributing to algal blooms and exacerbating any tendency toward eutrophication.

The human demand for food will increase fishing pressure, even with more comprehensive management and regulation of fisheries. Already overfishing has caused reorganization of oceanic and coastal ecosystems through removal of top predators (Scheffer et al. 2005), and additional effects are being seen as fishing effort shifts to smaller fish at lower trophic levels (Pauly et al. 1998). A worldwide increase in abundance of jellyfish in oceanic and coastal waters may be caused by removal of competition by fish, along with warming (Purcell 2005; Purcell et al. 2007). Jellyfish contribute little to fisheries.

Shoreline modification will accelerate, leading to installation of more hard edges and barriers (Bulleri and Chapman 2010). Armoring shores with seawalls and levees may accelerate as part of a strategy of adaptation to rising sea level, particularly in low-lying areas (Nicholls and Cazenave 2010). Armored shores can lead to increased and focused wave and tidal energy, causing erosion along unprotected shores. Restoration of marshes also alters shorelines, although it is generally done to improve or enhance estuarine ecosystems (Callaway 2005).

The increase in global population and trade has caused an increase in worldwide shipping and that trend is expected to continue. Besides the requirement for expansion of port facilities, shipping brings an unavoidable risk of accidents and oil spills that damage estuaries, especially marshes and other intertidal areas.

Global shipping also transports species between estuaries (Carlton and Geller 1993; Ruiz et al. 1999, 2000). Although regulations that require treatment of ships' ballast water may be effective in reducing this transport, the increase in shipping, particularly into ports that lack regulations or enforcement, will allow more transport of organisms. Certain introduced species have altered the physical structure of estuaries, notably plants that create dense beds (e.g., cordgrass; Callaway and Josselyn 1992; Crooks 2002; Levin et al. 2006; Silliman and Bertness 2004). Some bivalves, including the zebra mussel (Caraco et al. 1997) and the clams *Corbicula fluminea* (Phelps 1994) and *Corbula amurensis* (Nichols et al. 1990), have had strong impacts on water-column organisms through predation and competition. Other taxonomic groups have had big impacts (Purcell et al. 2007; Lehtiniemi and Gorokhova 2008), and the native faunas of some estuaries have been overwhelmed by introduced species (e.g., SFE, Cohen and Carlton 1998).

A catastrophic change in the physical configuration of an estuary has a low probability of occurring in any one year, but over a timescale of many decades it can become likely. For example, by definition a 100-year flood has a 1% probability of occurrence in any one year and is likely to occur at least once in the next 70 years. Catastrophes that can be anticipated include geomorphic rearrangement by large storms (Morton and Sallenger 2003), earthquakes (Mount and Twiss 2005), and tsunamis (MacInnes et al. 2009). These changes may or may not be reversible through intensive human intervention such as by repairing breaches in levees or seawalls.

4.22.4 Modes of Estuarine Response

The responses to long-term change are likely to differ greatly among estuaries in different regions. Some regions will see an increase in precipitation and others a decline, some regions will be harder-hit by strong storms than others, and rivers in some mountainous watersheds will see a shift to more runoff in winter and less in spring. The rate of sea-level rise will depend on local or regional vertical movements of the earth's crust. Estuaries at high latitudes will have a longer ice-free season. Estuaries in upwelling zones will receive a higher input of nutrients as upwelling strengthens.

The unique physical and geographic configuration of each estuary also influences its response to long-term change. For example, estuaries formed from river-derived sediment such as deltas and bar-built estuaries are particularly vulnerable to changes in freshwater flow, impoundment of sediments, sea-level rise, and alteration of longshore sediment transport by ocean waves. The ability of an estuarine species to extend its range depends on the distance to adjacent estuaries, outflow patterns, and ocean currents, as well as its ability to survive oceanic conditions.

The relative importance of climate and other anthropogenic effects will depend on the extent of human use of an estuary. Where estuaries or their watersheds have been extensively altered for human use, trends in human demand for freshwater, food, and land will be a key determinant of long-term change. In addition, human adaptation to climate change will entail alterations that also influence ecosystem function.

Moreover, changes that are expected within any one estuary will be concurrent, and their effects will interact (see Section 4.22.4.2. Interactions). These interactions are likely to play out in different ways in different estuaries.

Some likely differences among the responses of estuaries to climate change can be inferred from their heterogeneous responses to seasonal (somewhat predictable) and interannual (unpredictable) variation in inputs. For example, estuaries showed widely varying seasonal and interannual patterns of phytoplankton production, probably reflecting different controls on productivity (Cloern and Jassby 2008, 2010). Likewise, estuarine organisms can respond to freshwater flow by a wide variety of mechanisms that can even be of opposite sign (see Section 4.22.2.1.2 Freshwater, Salinity, and Mixing; Kimmerer 2002; Gillanders and Kingsford 2002).

Estuarine scientists usually study only one or a few estuaries, and comparisons among estuaries are valuable but infrequent (e.g., Boynton et al. 1982; Nixon 1988; Seitzinger 1988; Emmett et al. 2000; Cloern and Jassby 2008, 2010; Gillanders et al. 2011). This emphasis on particular estuaries reflects the heterogeneity among estuaries, their different responses to climate and other influences, and the differences in research topics. For example, eutrophication is arguably the process of greatest management concern in many estuaries in Europe and eastern North America, and therefore receives a lot of research attention. Eutrophication is much less prevalent, and therefore less often studied, in estuaries in western North America. The heterogeneity among estuaries and among the topics studied limits the scope of general statements on the effects of climate change on estuarine ecosystems.

4.22.4.1 Mitigation and Adaptation

Mitigation activities that affect estuaries directly include increases in the generation of renewable energy by dams and tidal and wave generators or by production of biofuel through harvesting or aquaculture. Each of these can exact penalties to the functioning of estuarine ecosystems. Dams alter hydrographs, and tidal and wave generators can kill estuarine organisms (Aprahamian et al. 2010). The use of large-scale coastal aquaculture to raise food or biofuels requires a large area with attendant loss of habitat and potential for eutrophication.

Adaptation in this context refers to actions to reduce deleterious effects of climate change at a local or regional scale (Scheraga and Grambsch 1998; Nillesen and van Ierland 2006). This may include abandoning areas that become unlivable because of changing climate, which is already

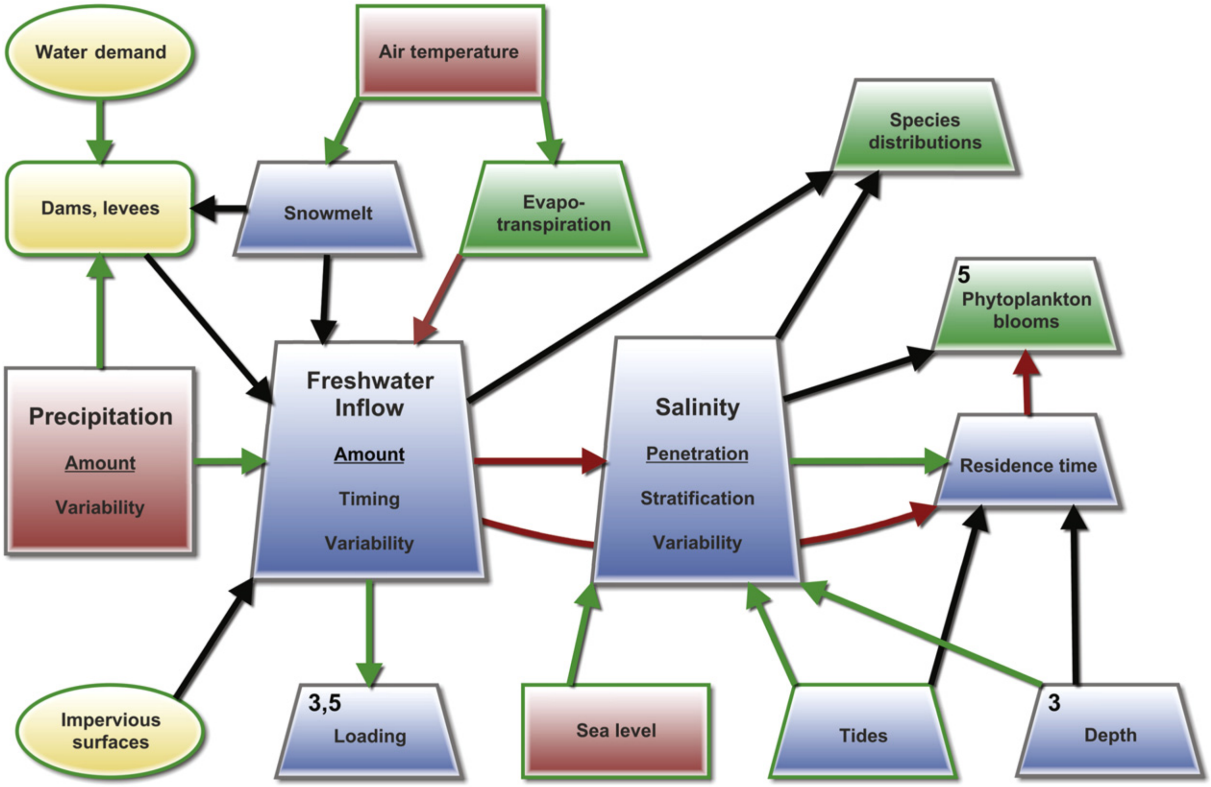

Figure 2 Schematic of the physical and biological responses of an estuary to changes in 'precipitation and freshwater runoff,' as described in Section 4.22.2.1 Physical Responses of Estuaries to External Influences. Boxes as in **Figure 1** plus blue trapezoids are physical responses to external influences including the 'salinity' gradient. Green trapezoids are biological responses, perhaps mediated by physical responses. Border colors as in **Figure 1**. Black arrows as in **Figure 1**. Green arrows indicate a positive effect as the influence increases. Red indicates a negative effect, which refers to the underlined quantities in the center boxes. Numbers in boxes link responses to other figures where processes are detailed.

occurring in the Mekong Delta and elsewhere (de Sherbinin et al. 2011). Less extreme measures include armoring to protect property against erosion caused by rising sea level and more powerful storms. In agricultural watersheds, adaptation to higher temperature and increased drought frequency may require increasing irrigation flows, further increasing demand for water, unless improvements in irrigation practices offset this increase. Desalination to offset loss of freshwater flow requires power and the disposal of brine.

Many adaptations will entail changes in policy and exacerbate conflict over dwindling resources, particularly where estuaries and their rivers cross international borders. Policy changes could include abandonment or reduction of environmental protection in favor of protecting human life and property, resulting in devastating alterations to estuaries.

4.22.4.2 Interactions

In general, the anticipated long-term changes in climate and human influences are clear (see Section 4.22.3); the processes that control estuarine responses to those influences are understood in broad terms (see Section 4.22.2). However, these effects will not occur in isolation. The network of interactions among climate variables, other long-term trends, and physical and biological responses are complex and our summary of interactions is necessarily simple and incomplete. Each subsection proceeds generally from the immediate effects of climate forcing, to the effects of human activities, and then to the interactions.

4.22.4.2.1 Precipitation, Freshwater Runoff, and Salinity (Figure 2)

Climate and human activities influence the temporal pattern and quantity of runoff into estuaries, with numerous ramifications for ecosystem function. Annual precipitation, timing of runoff peaks, and variability because of seasonal patterns and storms, all of which can have climate-based trends, determine the water available for runoff. Rising temperature will increase evapotranspiration, which increases uptake of water by plants from groundwater, reducing flow into estuaries (Nijssen et al. 2001).

Increasing demand for water, increased evapotranspiration, and seasonal shifts and unreliability in precipitation will stimulate construction of dams to capture more water for times of low flow. Although dams dampen seasonal variability in freshwater flow, greater variability in precipitation and construction of impervious surfaces and levees will increase short-term variability by hours to days. Local diversions of water from rivers and groundwater pools will further deplete the water available to flow into estuaries, especially during droughts.

Changes in runoff will be accompanied by changes in loading of materials such as sediments and nutrients. However, these loadings in general are more influenced by regional or local human activities such as dams and agriculture than by changes in flow patterns.

Changes in freshwater flow into estuaries have numerous consequences, and numerous causal pathways to those consequences (see Section 4.22.2.1.2.). The influence of freshwater flow on salinity patterns in an estuary depends on bathymetry, sea level, tides, and wind speed and direction. Rising sea level would increase salinity in the absence of other changes but in most estuaries it probably has a minor influence on long-term change compared with alterations in flow and bathymetry.

The physical changes associated with increasing freshwater flow induce a cascade of biotic responses. In tidal freshwater regions flow directly influences distributions and residence time of organisms. In more saline areas the influence of flow is mediated by salinity. Shifts in the salinity gradient alter the distributions of benthic and marsh biota through salinity tolerance and species interactions such as predation and competition. While pelagic species are less affected by the movement of the salinity gradient because they move with the water (Laprise and Dodson 1993), high flows can flush pelagic organisms from an estuary and diminish their estuarine populations.

Variation in freshwater flow into estuaries affects phytoplankton production (see Section 4.22.2.2), which is the predominant source of available organic carbon for most estuarine ecosystems. In many river-dominated estuaries, freshwater flow stimulates primary production. Fish and large invertebrates may grow and reproduce faster if high flow stimulates primary production, increasing production up the foodweb. Alternatively, estuarine animals may respond to changes in physical habitat; for example, through retention mechanisms or changes in the overlap of favorable salinity with favorable bathymetry (Kimmerer et al. 2009).

4.22.4.2.2 Sediment Supply, Transport, and Loss (Figure 3)

River flow controls much of the loading of sediment into an estuary (see Section 4.22.2.1.3.). Sediment loading may increase with an increase in peak river flows, or under dry conditions with an increase in the frequency of fires that expose land to greater erosion. Dredging, mining, and construction of hard or impervious surfaces in the watershed can increase sediment loading. In many of the world's rivers, though, the predominant trend is likely to be a decrease in sediment loading because of the construction of dams that trap sediments.

Within an estuary the short-term balance between erosion and deposition is controlled by the strength of tidal and river-derived currents and wind waves and how these interact with bathymetry. Sea-level rise, an increase in wind speed or peak storm intensity, armoring as a defense against local erosion, and dredging will shift this short-term balance toward erosion.

The long-term balance between supply and loss to the ocean and to burial within the estuary depends on the short-term balance, which governs how much of the sediment is suspended in the water (Schoellhamer 2011). The long-term balance also depends on residence time of suspended sediment in the estuary. Sediment can be trapped by two-layer estuarine circulation, which usually increases with freshwater flow and with increasing water depth (see Section 4.22.2.1.2.). Estuaries that are open only seasonally may remain open for longer periods as the sand supply dwindles and peak wave height increases, although decreasing river flow may shorten the open period.

Turbidity caused by suspended sediment can limit growth rates of plants, including phytoplankton and seagrass (Goosen et al. 1999). Turbidity also interferes with visual detection of prey by predators, creating a refuge for the prey (De Robertis et al. 2003). Increasing water depth caused by tidal scouring of channels, in some places accelerated by dredging, can change tidal circulation, salt balance, and the movement and retention of planktonic and epibenthic organisms (Hansen and Rattray 1965; Monismith et al. 2002).

4.22.4.2.3 Vegetated Beds (Figure 4)

Marshes, mangrove forests, and seagrass beds exist in a dynamic equilibrium of sediment erosion and deposition. Long-term changes in factors that affect sediment budgets (see Section 4.22.4.2.2.) are essential to the development and stability of vegetated beds. Conversely, vegetated beds reduce current speed and wave height, capturing sediment and resisting erosion.

Accretion of marshes is faster where sediment supply is adequate and the tidal range is large enough to transport the sediment quickly (Simas et al. 2001). If the sediment supply is inadequate for marsh elevation to keep up with rising sea level, marshes may 'move' up-slope as upland is replaced by marsh and low marsh by open water. However, this will be limited in many estuaries by the slope of the land and the extent of hardened shoreline (Osterkamp et al. 2001; Chust et al. 2011).

Vegetated beds are vulnerable to other effects. For example, seagrasses may be affected simultaneously by increased CO_2 and temperature, which enhance growth; increased sea level, which decreases light availability; increased strength of tidal currents; and increased salinity penetration, which limits the range of seagrass beds through physiological tolerance (Short and Neckles 1999). However, local anthropogenic impacts such as habitat destruction, nutrient loading, and sediment discharge may cause a much greater loss of submerged and marsh vegetation than climate change. Nutrient loading can stimulate phytoplankton blooms which reduce light penetration and degrade vegetated beds. Direct human impacts have devastated seagrass beds in some areas (Orth et al. 2006), and a recent estimate of global rate of loss was an astonishing 7% per year (Waycott et al. 2009). Similar rates of loss apply to mangrove forests, with the principal cause being development (Polidoro et al. 2010). In both cases, valuable ecosystem services such as nutrient cycling and shoreline protection are lost.

4.22.4.2.4 Eutrophication (Figure 5)

Eutrophication in estuaries is usually caused by the loading of nutrients or organic matter from land (Ryther and Dunstan 1971; Cloern 2001). Organic loading stimulates estuarine eutrophication directly, and nutrient loading stimulates eutrophication by enhancing phytoplankton growth. Although the cause of eutrophication is straightforward, reducing it has proved difficult, and several long-term trends suggest that this problem will get worse (Diaz 2001). In developed countries

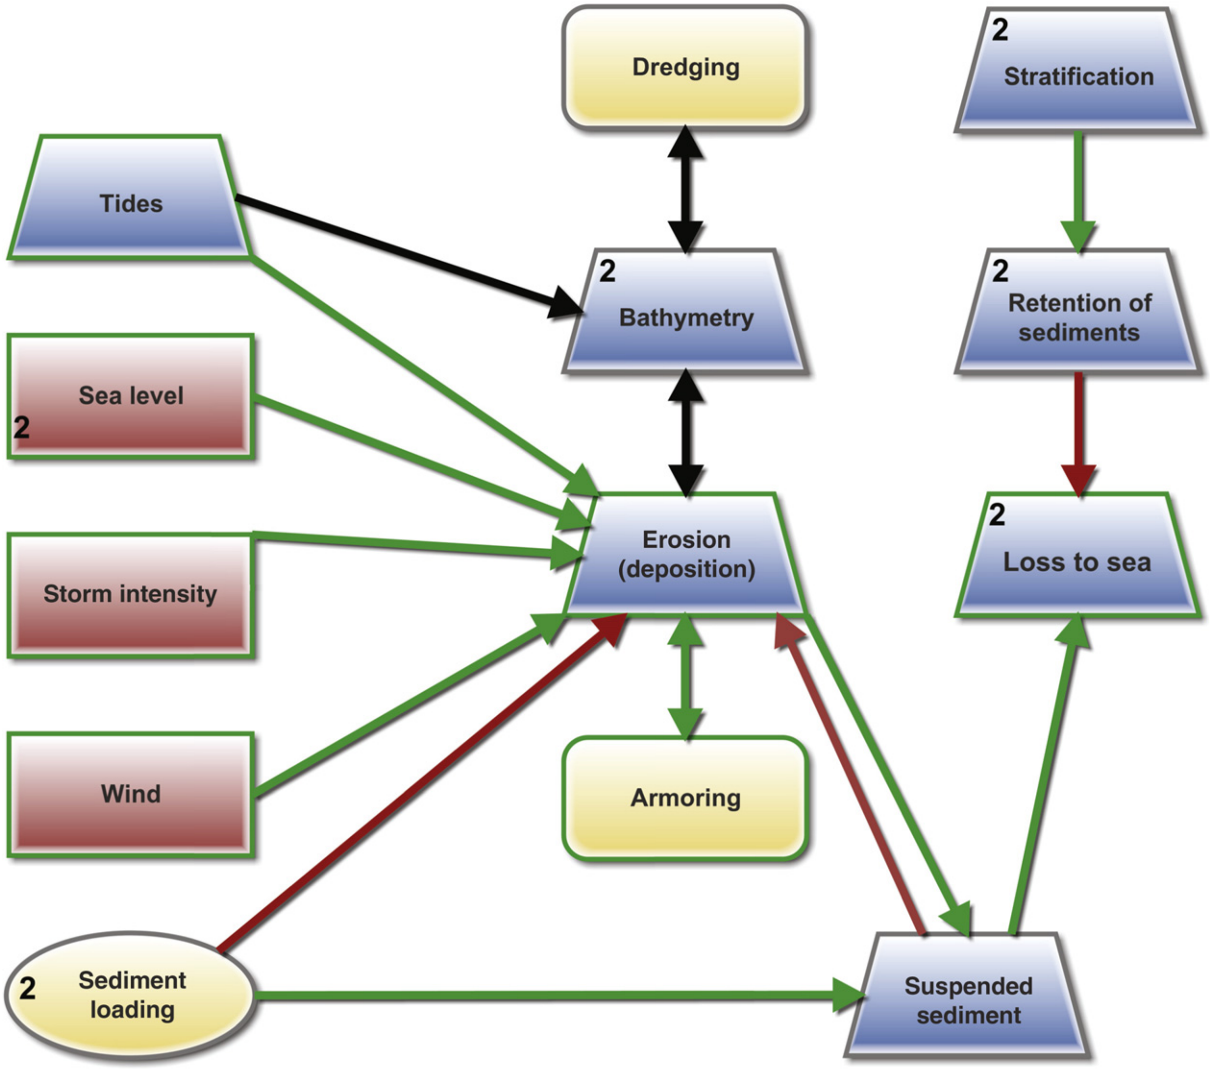

Figure 3 Schematic of the effects of changes in 'sediment supply, transport, and loss' on sediment deposition and erosion within an estuary, as described in Section 4.22.4.2.2 Sediment Supply, Transport, and Loss. Boxes, arrows, and numbers are as in **Figures 1 and 2**. Green is positive for erosion and negative for deposition. Red is negative for erosion and positive for deposition.

nutrient reductions achieved through improved treatment have been be offset by intensification of loading from non-point sources such as farms (Kemp et al. 2005).

Long residence time allows for production and decomposition of organic matter, and persistent stratification increases local residence time for sinking particles (see Section 4.22.2.1.2. Freshwater, Salinity, and Mixing), whereas turbidity caused by suspended sediment inhibits primary production. Therefore, either increases or decreases in freshwater flow could exacerbate eutrophication in estuaries, as could a reduction in turbidity because of decreases in suspended sediment.

Hypoxia is a persistent problem in many estuaries and coastal regions (Diaz and Rosenberg 1995; Diaz 2001; Conley et al. 2009), particularly in places in which eutrophication combines with restricted circulation such as in stratified, deep basins. Few benthic organisms can survive extended periods of hypoxia, and the hypoxic region is excluded as productive habitat (Breitburg 1992; Diaz and Rosenberg 1995). Increasing temperature raises microbial metabolic rates and can increase the frequency or extent of hypoxia.

The frequency of harmful algal blooms may be increasing worldwide, partly owing to high nutrient concentrations and high temperature (Anderson et al. 2002; Paerl and Huisman 2008). These blooms can reduce production of fish and other valued estuarine biota.

Increases in contaminant loading are also likely; for example, from urban runoff and intensified agricultural production. We do not consider contaminants further because their effects are often site-specific and sporadic.

4.22.4.2.5 Species Shifts (Figure 6)

Changes in range or phenology caused by regional warming, competition with introduced species, or other trends can increase or decrease the abundance of a species in an estuary and allow for colonization from other estuaries. To colonize an estuary, a founding population must survive transport from

one estuary to another, so colonization may be more frequent where estuaries are large, close, and hydrologically linked, as in the southeast United States. However, colonizers may be near the limit of their thermal tolerance. Species introduced artificially from another estuary of similar climate (e.g., Cordell et al. 2008) are more likely to find favorable conditions and quickly integrate into their new environment than natural colonizers (Cordell et al. 2008). Introductions are likely to remain the major mechanism for colonization in many estuaries, and are also likely to accelerate colonizations that would eventually occur through range shifts.

Successful colonization depends on environmental conditions such as suitable temperature, salinity, sediment type, flow conditions, and residence time. Interactions with local species are equally important (e.g., food supply, predators, shelter from predation, harvest). These physical and biological attributes are difficult to assess even in well-studied situations because of the myriad and often subtle species interactions

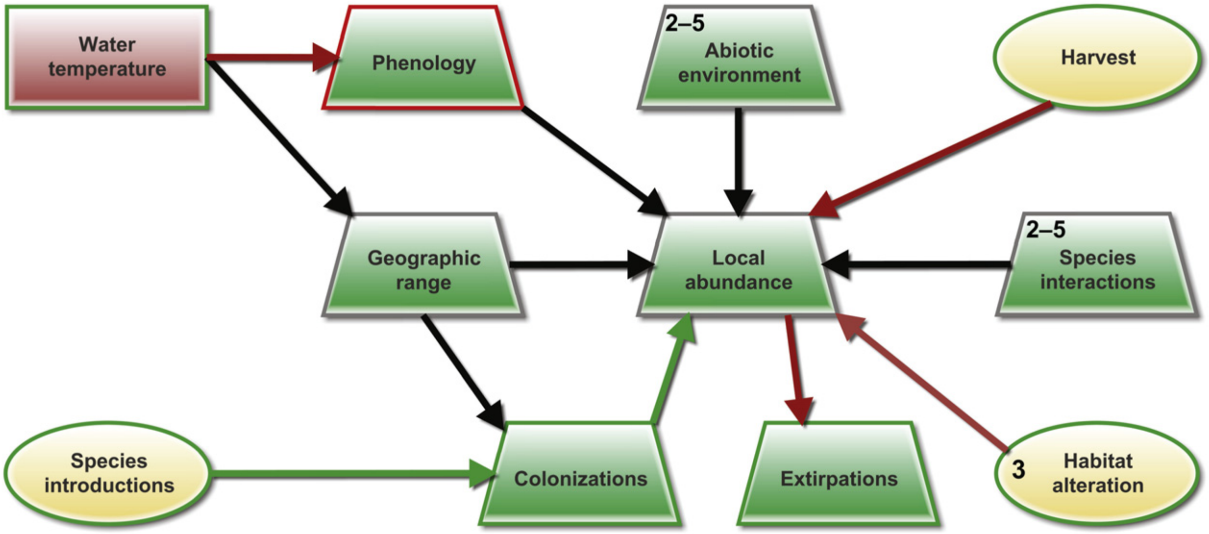

Figure 6 Schematic relating climate, and other long-term, changes to shifts in 'species composition' within estuaries, as described in Section 4.22.4.2.5. Boxes, arrows, and numbers are as in **Figures 1–4**. Except for the 'species interactions' box, this diagram refers to a single species in a single estuary.

such as concurrent shifts in range and phenology of predator and prey. For example, relative changes in phenology between a copepod and its gelatinous predator in Narragansett Bay, apparently caused by warming, have intensified the predator–prey relationship, resulting in seasonal extirpation of the copepod (Costello et al. 2006). Intertidal mussels on a rocky shore could withstand increasing temperature only in the absence of predators (Harley 2011). Thus, the 'species interaction' box in Figure 6 hides a tangle of interactions.

The potential also exists for long-distance effects of changes in species abundance. For example, some ducks and shorebirds migrate thousands of kilometers between summer and winter habitats. Some of these species are important components of estuarine ecosystems (e.g., Poulton et al. 2002), and changes in their abundance caused by events in their alternate habitat would affect those ecosystems.

4.22.4.3 Catastrophes

Although catastrophic events such as earthquakes and floods are inherently unpredictable, often their cumulative probability over decades can be calculated. Mount and Twiss (2005) estimated a two-thirds probability by 2050 of multiple failures among weakened levees in the California Delta, cutting off a water supply for about 23 million residents and about half of California's agriculture. This scenario is reminiscent of Hurricanes Katrina and Rita in the Gulf coast (Day et al. 2007) and the recent tsunamis in Indonesia (2010) and Japan (2011). The impact of catastrophes obviously depends on the particular characteristics of the estuary.

Catastrophic change may also occur when systems are pushed from one stable state into another. A slight change in salinity in a Danish fjord, caused by a decision to open a sluice gate to increase exchange with the ocean, transformed the estuary from a turbid state with high phytoplankton biomass to a clear state with numerous benthic filter-feeders (Petersen et al. 2008). Although examples of such apparently reversible state changes are uncommon, similar but irreversible state changes can accompany changes such as the spread of invasive species (see Section 4.22.4.2.5. Species Shifts (Figure 6)).

4.22.4.4 Application to Particular Estuaries

Here we describe anticipated responses to long-term change of three disparate estuaries. The San Francisco, Chesapeake, and Murray–Darling estuaries are large and intensely studied, with recent published reports on observed and predicted long-term change. Each has prominent intergovernmental agencies responsible for stewardship (e.g., the California Delta Stewardship Council, the Chesapeake Bay Program, and the Murray–Darling Basin Authority).

4.22.4.4.1 San Francisco Estuary

The major concerns for the SFE focus on the tidal freshwater region, a key element of California's water supply system, and the conflict between water supply and freshwater flow into the estuary. Impediments to solving this conflict in the long term include the historical loss of most of the fringing marshes to development, the prevalence of nonnative invasive species, the variable flow regime with a trend to earlier spring runoff peaks, and the seismic vulnerability of levees protecting subsided farmlands.

The SFE, which includes San Francisco Bay and the California Delta, is one of the largest and most-studied estuaries in North America. The SFE is a heavily urbanized estuary with a strongly agricultural watershed. Most of the freshwater for the estuary originates as snowmelt in the Sierra Nevada and flows through the Delta of the Sacramento and San Joaquin Rivers. The climate is Mediterranean, with a long summer dry season and a winter wet season with up to ninefold variation in annual runoff. Much of the annual flow is trapped behind dams for use through the dry season, and the lower reaches of the watershed are laced with canals and diversions. The intensive use of the watershed, coupled with interannual variability in seasonal water supply, is the main reason for the intense conflict over water in California.

A recent synthesis of information from an interdisciplinary modeling effort projected the effects of climate change on the SFE and its watershed through the twenty-first century (Cloern et al. 2011). Forecasts were based on two IPCC scenarios, one of moderate warming (PCM-B1) and the other of rapid warming and a decrease in precipitation (GFDL-A2), compared to a baseline period of 1970–1999. Cloern et al. (2011) used a series of models to estimate regional air and water temperature, precipitation, runoff, operation of the water storage and delivery system, sea level, and estuarine salinity and temperature. The forecasted changes were placed in the context of a system that has been radically altered by human activities.

Results for the A2 scenario showed a 0.4 °C/decade increase in regional air temperature, a 28-mm/decade decrease in precipitation, and a 12-cm/decade increase in sea level (see Cloern et al. 2011 for confidence limits). Estimated runoff if there were no dams or diversions ('unimpaired' runoff) decreased by 2%/decade, and the percent of runoff from snowmelt decreased by 1%/decade. Temperature in the Delta increased by 0.3 °C/decade and estuary-wide mean salinity by 0.5/decade (practical salinity scale). The cooler, wetter B1 scenario forecasted similar patterns but with smaller magnitude for most variables, and the changes in precipitation and runoff were not distinguishable from zero.

Increases in extremes were also predicted, including high water level leading to flooding, and high temperature in the Delta, imposing thermal stress on the endangered delta smelt *Hypomesus transpacificus*. The frequency of floods in the lower watershed will decrease, to the detriment of estuarine fishes that spawn or rear on floodplains such as the native Sacramento splittail *Pogonichthys macrolepidotus*.

Broader conclusions were that the Delta would become warmer, clearer, and more saline. These trends would reduce the sustainability of delta smelt, which is sensitive to high temperature, avoids high salinity, and is most abundant in turbid water (Feyrer et al. 2011).

Restoration activities are being planned and conducted with little consideration of anticipated changes in hydrology, temperature, and sediment supply, which may limit the feasibility of achieving restoration goals. Depletion of groundwater in the SFE's watershed (Famiglietti et al. 2011) indicates that California's water budget is oversubscribed. Changes in precipitation and seasonal runoff, together with the increased frequency of extreme flows, will complicate the water supply picture and aggravate the ongoing conflicts over water.

Cloern et al. (2011) explicitly left out consideration of human activities that might change the outcomes of the model scenarios, as well as potential impacts on marshes and on the seaward, more saline reaches of the estuary. California's water supply system could adapt to much of the change in flow timing and quantity while maintaining at least some flows for environmental conservation (Medellin-Azuara et al. 2008). The strong seasonal pattern in precipitation is the primary driver of seasonal and decadal variability in flow, whereas dams and diversions have mainly affected long-term trends (Enright and Culberson 2010). However, substantial alterations in the structure and operation of California's water supply system are being planned, notably a massive water diversion system to alleviate problems with pumping water from the tidal freshwater part of the system (Lund et al. 2007). The effect on estuarine salinity will depend on design of this system and its operating rules. Multiple seismically driven levee failures (Mount and Twiss 2005) would cause a large, immediate influx of saline water. Forecasts of salinity distributions based on climate change alone seem incomplete.

Most of the environmental problems of the SFE have been either caused by, or solutions are impeded by, introduced species (Nichols et al. 1990; Brown and Michniuk 2007; Lund et al. 2007). Introduction of additional, influential species such as the quagga mussel are likely, further compounding the uncertainty of climate projections.

A projection of extent and frequency of inundation of land showed large areas at risk, and predicted that the 100-year flood of year 2000 would be a 1-year event by mid-century (Knowles 2010). A review by Parker et al. (2011) addressed effects of climate change on tidal marshes, emphasizing sea-level rise as well as temperature and salinity. Rising sea level will cause loss of marsh area because the present-day sediment supply is inadequate to support accretion of marshes (Knowles 2010) and hard structures limit upland development of many marshes. Rising temperature and salinity are forecasted to cause physiological stress and reduce diversity of marshes (Parker et al. 2011). This review does not consider the likely decrease in sediment supply caused by trapping behind dams (Schoellhamer 2011) or in flooded islands (Mount and Twiss 2005).

4.22.4.4.2 Chesapeake Bay

Much of the concern for management in the Chesapeake Bay has focused on eutrophication and its influence on or interaction with hypoxia, loss of seagrass, and loss of oyster reefs (Breitburg 1992; Kemp et al. 2005). Non-point source inputs of nutrients have slowed the reduction of nutrient loading achieved through improved wastewater treatment (Kemp et al. 2005).

A recent review by Najjar et al. (2010) summarized the likely interactive impacts of end-of-century increases in temperature (2–6 °C), sea level (0.7–1.6 m), and precipitation on living resources, particularly eelgrass, fish, and shellfish. The general projection is for a continued trajectory toward a plankton-dominated, eutrophic system. Precipitation in the basin is expected to increase, particularly in winter–spring, with an increase in the frequency of high-rainfall events. The change in seasonal pattern of precipitation, together with increasing evapotranspiration in the watershed due to higher temperature, will sharpen the seasonal difference between high winter flows and low summer flows. Sea-level rise will increase salinity penetration into the Bay and increase the tidal range, resulting in stronger vertical mixing. In the brackish northern part of the Bay this tendency will be offset by higher spring flows, likely resulting in stronger and more persistent spring–summer stratification. The combination of stronger tidal currents and greater sediment loading owing to erosion in the watershed and extreme winter flows will likely result in more suspended sediment in the water column, although the interactions among factors affecting sediment make quantitative predictions difficult.

Loading of nutrients and organic matter from nonpoint systems will increase. Increased temperature and nutrient loading will cause spring diatom blooms to begin earlier and produce more biomass, allowing an earlier start to summer hypoxia. This tendency will be strengthened and extended by the increased strength of stratification. In addition, because respiration increases more steeply than photosynthesis with increasing temperature, the estuary may shift toward net heterotrophy and possibly lower foodweb efficiency and an increase in blooms of harmful algae.

Growth rates of vascular plants including submerged aquatic vegetation (SAV) and marsh vegetation will likely increase with increasing CO_2. Yet the geographic coverage of eelgrass and other SAV will likely continue to decline with increasing turbidity because of high phytoplankton biomass. In addition, eelgrass, at the southern limit of its range in the Chesapeake Bay, will likely suffer more overgrowth by epiphytes and diebacks due to warming. An increase in the duration of low-flow periods during droughts could increase water clarity and possibly benefit SAV. However, wetlands may be unable to keep up with the rate of sea-level rise through accretion of sediments.

Harvested species of fish and shellfish are subject to several long-term influences. In particular, habitat for fish and some shellfish will shrink as the extent of hypoxia grows (Breitburg 1992). Loss of oysters to overharvesting and disease may have shifted the entire system into a more eutrophic stable state (Kemp et al. 2005). Similarly, loss of seagrasses owing mainly to shading by phytoplankton has resulted in an alternative stable state, reversible only through a reduction of phytoplankton blooms (Kemp et al. 2005). Nonlinear interactions within this complex ecosystem, and the likelihood of range extensions into the Chesapeake Bay by potentially influential species, preclude confident predictions about future trajectories.

4.22.4.4.3 Murray–Darling System, Australia

The Murray–Darling river–estuary system illustrates the effects of long-term change in arid areas (Kingsford et al. 2011). Apparently most of this trend is human-driven. A severe drought in southeastern Australia from 1997 through mid-2010 was followed by floods in 2010–11. Total precipitation in the basin is not expected to decrease with climate change (Sun et al. 2011), and similar droughts have occurred in the past (Roderick 2011). What is unprecedented is the low flow in the river; because of water withdrawals for irrigation, almost no freshwater flowed into the estuary during the last 4 years of the drought (Webster 2010).

The estuary comprises two broad, shallow lakes and a long, narrow lagoon (the Coorong) behind a barrier beach. Although not urbanized, it is a popular recreational site and an important habitat for migratory waterbirds. Barrages installed to guide river flow to the mouth also restrict flows among the basins. The barrier island and river mouth are in a continual state of flux, exacerbated by the barrages (Bourman et al. 2000).

Toward the end of the drought the southern Coorong was intensely hypersaline because of high evaporation and sluggish exchange. The salinity of greater than 100 mg/l exceeded the tolerance of nearly all estuarine and marine organisms (Webster 2010). Lowered water levels exposed toxic sulfate soils and the Australian government spent ~A$1B on restoration without addressing the shortfall in flow (Kingsford et al. 2011). During subsequent floods the salinity has declined and valued species of fish and birds have returned to the Coorong.

Responses to the environmental problems in the Coorong were constrained by the near-total lack of freshwater above the minimum demanded for irrigation. Reallocation of the water supply is being considered (Roderick 2011; Kingsford et al. 2011), as is a pipe to connect the Coorong directly to the ocean (Webster 2010).

Thus, the Murray–Darling system illustrates how human uses of water can lead to severe degradation in an environmentally stressed estuary. This example also shows how local issues direct research; the emphasis in the relevant reports found on this system was on flows and barrages, with little mention of potential effects of warming, ocean acidification, or sea-level rise.

4.22.4.4.4 Summary of Case Studies

What is striking when comparing these three estuaries is the difference among the long-term processes dominant in each estuary: water supply and introduced species in the SFE, eutrophication in the Chesapeake Bay, and farming in an arid region in the Murray–Darling system. These estuaries are at about the same latitude, have temperate climates, and are in developed countries. The difference in emphasis is not caused by lack of information; in particular, the Chesapeake Bay and the SFE are perhaps the world's most-studied estuaries after the Baltic Sea. Rather, it reflects the prudent consideration of local conditions when researching and managing the effects of long-term change.

'Climate change' is a hot topic. Much less attention has been given to other long-term changes with similar magnitude and timescales (see Section 4.22.3.2 Direct Human Effects). All three studies presented here, particularly the Murray–Darling, emphasize the point made by Vörösmarty et al. (2000) more than a decade ago that local and regional human activity can dominate the trajectory of long-term change.

4.22.5 Implications for Ecosystem Functions and Services

Predicting the future of estuarine functions and services is difficult. First, projections of the state of natural–human systems over decades and longer are uncertain. Second, unforeseen changes in policy, technology, economics, and society will affect how estuarine services are used and managed. Third, each estuary is unique, as is its response to change. Fourth, our understanding of climate, other human influences, and ecosystem functions will improve along with efforts to mitigate and adapt.

Despite the uncertainty, some long-term influences have predictable trends with known risks that are likely to occur in many estuaries (see Sections 4.22.3.1 and 4.22.3.2, Table 2). These influences include temperature, sea level, ocean acidification, human population growth, habitat alteration, and introduced species. Rising temperature affects estuarine functions through physiological and phenomenological changes and range shifts, and through effects on river flow. Rising sea level increases erosion and degrades vegetated beds, shorelines, and structures. Ocean acidification reduces growth rates of oysters and mussels. Population growth increases the demand for water and other estuarine services. Increased demand for water reduces freshwater flow into estuaries. Habitat alterations eliminate vegetated beds and thereby diminish estuarine services such as disturbance regulation and food production. Introduced species alter community composition and biotic interactions but with less predictable consequences. All of these proximate impacts are likely to occur or are occurring in many estuaries, but outcomes for a particular estuary are less certain.

We have identified and diagrammed five mechanisms (see Section 4.22.4.2, **Table 1**, **Figures 2–6**) by which long-term influences amend estuarine functions and thereby degrade estuarine services in many estuaries: changes in freshwater flow, supply and loss of sediment, alteration of vegetated beds, eutrophication, and shifts in species. Each of these mechanisms applies to many estuaries, and the mechanisms can be used to deduce the likely long-term trajectory of an individual estuary.

Globally the supply of water falls short of human demand, and in most estuaries freshwater inflow will likely decrease. The joint effects of increased demand and reduced supply due to reduced precipitation and warming in the watershed (4.22.4.2.1) will exacerbate shortages and increase conflict in many if not most estuaries. Loss of inflow can lead to the collapse of functions and the complete loss of services, although the Murray–Darling system showed remarkable resilience following a decade-long lack of flow (see Section 4.22.4.2.).

The amount of available sediment in estuaries will decline globally as a result of sea-level rise, erosion, and damming and reduction in flood flows. The resulting reorganization of bathymetry and loss of shoreline and marsh habitats will impair estuarine services, particularly those provided by marshes and vegetated beds (**Table 1**). Reductions in turbidity will increase risk of eutrophication and alter predator–prey relationships. A decline in turbidity over the past three decades in the SFE is associated with declines in the endangered delta smelt (see Section 4.22.4.4.1.).

Habitat alteration for urban, agricultural, and other uses also eliminates ecosystem services provided by vegetated beds. Globally these habitats continue to decline. The interaction of habitat alteration with increased erosion resulting from sea-level rise, loss of sediment, and reductions in freshwater inflow leads to a continuing loss of these estuarine services. These losses are particularly apparent in south Asia, where removal of mangrove forests for aquaculture has resulted in losses of services such as shoreline protection and nursery habitats (Polidoro et al. 2010).

In eutrophic estuaries, ecosystem services are already under threat because of habitat degradation through shading of seagrass beds and development of harmful algal blooms and hypoxia, with attendant loss of benthic assemblages and habitat for higher trophic levels (see Section 4.22.4.2.4.). The principal long-term drivers of eutrophication are nutrient and organic loading, but stratification and therefore freshwater runoff are important factors, and temperature, habitat alteration, and turbidity contribute. Eutrophication can impair all of the ecosystem services listed in **Table 1**. For example, the loss of seagrass beds in the Chesapeake Bay, owing partly to eutrophication, eliminated physical habitat and a significant food resource for many harvested bay and coastal species.

Species distributions globally are moving poleward in response to warming, and flora and fauna are becoming homogenized through introductions. Species gains and losses will likewise continue in most estuaries through some combination of range shifts and introductions (see Section 4.22.4.2.5.). Overharvest may accelerate changes through alteration of trophic structure and removal of predators and competitors of potential colonizers. Further extirpations and even extinctions are likely.

General patterns and mechanisms of estuarine responses to changes in climate and other influences, such as those discussed in the preceding and in Section 4.22.4, can be used to establish a suite of tools (**Figures 2–6**) and concepts that researchers, managers, and policy makers can draw on in characterizing the attributes, mechanisms, and likely responses of a specific estuary and in designing management actions that will be effective in the long term. Widespread or general trends and mechanisms such as those summarized herein can be used as a starting point, provided the existing state of the estuary and the current stresses it faces are understood, and the parallel roles of climate and local human actions are considered.

The site-specific character of many of the responses to long-term change could be used to advantage. Local action will be needed to address the consequences of the global failure to act. Many governments and populations around estuaries have established sophisticated arrangements for stewardship and adaptation. These arrangements have led to increases not only in protection and restoration, but also in monitoring and research to understand these valued estuarine services, as well as public knowledge and understanding of the repercussions of long-term changes. These trends will help in understanding, mitigating, and adapting locally to the anticipated global loss of estuarine services.

4.23.1 Introduction

Climate change is already being experienced in the Arctic, with implications for ecosystems and the human communities that depend on them (ACIA 2005; Huntington et al. 2007; IPCC 2007b; Furgal and Prowse 2008). Temperatures in the Arctic have been increasing at twice the global average (IPCC 2007a; Manabe et al. 2011), recent years have witnessed an unprecedented reduction in summer sea ice cover, permafrost is melting in some regions (Post et al. 2009), and extreme weather conditions have been described as being more unpredictable and frequent (IPCC 2007b). Indigenous peoples throughout the Circumpolar North have a profound interdependence with the natural environment, and many are already experiencing threats to their livelihoods – and lives – from the effects of climate change.

In Canada, the majority of the Inuit population lives in small, remote, coastal communities, and continues to depend on the harvesting of fish and wildlife for food security, income, and cultural well-being (AHDR 2004; Nuttall et al. 2005). This high dependence on the environment has made Inuit particularly susceptible to climate change, which is experienced together with socioeconomic, political, and cultural transformations (Anisimov et al. 2007; Lemmen et al. 2008). Compromised food security and health status, loss of life and serious injury, constrained transportation access and travel routes to hunting areas, and inability to practice traditional cultural activities have been documented across the Arctic, with the possibility of continued change into the foreseeable future with further effects on Inuit livelihoods (Furgal and Prowse 2008; Holland et al. 2010).

Research on climate change in the Arctic has provided considerable information about the implications of climate change for physical and biological systems. More recently there has been interest in the implications of climate change for northern people, their livelihoods, and their capacity to deal with and adapt to changing conditions. To understand how climate change is likely to affect people and communities requires knowledge of how people experience and respond to changing conditions, including the role of nonclimate factors (e.g., local economy, sociopolitical, cultural) (Duerden 2004; Ford and Smit 2004; McCarthy and Martello 2005). Studies adopting this perspective have been undertaken in Arctic communities from Alaska and Canada, Greenland and Iceland, as well as Norway, Finland, Sweden, and Russia (Hovelsrud and Smit 2010).

This chapter summarizes findings about the vulnerability and adaptation of arctic communities in the face of changing climatic conditions, with a focus on Inuit communities in Canada. The chapter first provides a brief overview of climate change and impacts in the Arctic, and outlines the evolution of analytical approaches to assessing vulnerability, noting the main features of the framework on which most of the community studies were based. Key vulnerabilities evident in the communities are then described, with detailed examples drawn from selected Canadian case studies. The chapter concludes with an assessment of the prospects for arctic communities to adapt to ongoing changes in climate-related conditions.

4.23.2 Climate Change Impacts in the Arctic

Climate change scenarios indicate that by the 2020s annual mean temperatures in the Arctic could increase in the order of 2 °C, with the greatest increases projected to occur during winter. Precipitation is expected to increase by up to 8% (IPCC 2007a). As with conditions already experienced, these changes will vary from one region to another (Furgal and Prowse 2008). Nonetheless, some broad impacts of climate change are projected, particularly in the cryosphere, which is crucial to ecosystem dynamics in arctic regions and is sensitive to changing climate.

Sea ice, a major component of the cryosphere, has already demonstrated significant responses to warmer climate. Arctic sea ice extent at the end of the melt season in September has declined sharply over the past decade and this trend is expected to accelerate in the future as a result of warming temperatures,

http://dx.doi.org/10.1016/B978-0-12-384703-4.00439-1

hastening the ongoing transition toward a seasonally ice-free Arctic ocean (Stroeve et al. 2008). Moreover, ice cover is increasingly dominated by thin, first-year ice (ice formed during the previous autumn and winter) that is susceptible to melting out in summer. Thin ice is also more vulnerable to strong winds and anomalous summer temperatures. It is believed that warming of the Arctic has reduced the likelihood of cold years that could bring about temporary recovery of the ice cover (Stroeve et al. 2012).

Snow cover plays an important role in the climate, hydrological, and ecological systems of the Arctic and other regions. Snow cover affects the surface energy balance (e.g., reflectivity), water balance (e.g., water storage and release), thermal regimes (e.g., insulation), and vegetation and trace gas fluxes (Callaghan et al. 2011). Research has also demonstrated the importance of snow cover to nutrient cycles (Sullivan et al. 2008) and carbon budgets in the Arctic (Welker et al. 2000). Snow cover is decreasing in most regions of the Arctic, especially in spring, in response to warming temperatures (Kundzewicz et al. 2007).

Glaciers and Ice Sheets are also part of the cryosphere–hydrosphere, and changes in them affect the magnitude and timing of river flows and sea level. A large number of Canada's glaciers and ice caps are located in Arctic and Subarctic regions. Significant retreats have been documented in glacier fronts and volume since 1920 (Furgal and Prowse 2008).

Permafrost or frozen ground is the norm throughout most of the Arctic, and it too plays an important role in northern hydrology and ecosystems. There is evidence of widespread permafrost warming and degradation, reflected in increased summer thaw penetration, expansion of the active (freeze–thaw) layer, and contraction of the area of permafrost (Burn and Kokelj 2009; Post et al. 2009). These trends are expected to continue with climate change, evident in degradation of continuous to discontinuous permafrost, and the disappearance of discontinuous permafrost in the southern zones (Zhang et al. 2008). The thawing of permafrost is expected to release large pools of carbon, a feedback to the climate system (Schuur and Abbott 2011).

Rivers and Lakes are expected to have a shortened ice season and thinner ice cover in the winter. Changes in glaciers, permafrost, and snow and ice dynamics will all affect the hydrologic system, with implications for freshwater discharge and flow regimes (Kundzewisz et al. 2007).

Coasts represent the zone of interaction between marine and terrestrial physical and biological systems and the zone where human occupancy is concentrated. Projected rises in sea level are expected to affect Arctic coastlines, notably through flooding and erosion. In some areas, effects of sea level rise are moderated by isostatic rebound, whereas in other areas rising sea levels are exacerbated by coastal subsidence. Coastal erosion can be affected by sea level rise, and it is accentuated by permafrost degradation, reduction in the extent of sea ice cover, and changes in the frequency and severity of storms (Lantuit and Pollard 2008; Overeem et al. 2011).

Ecosystems respond to changes in the physical environment. It was expected, and has been documented, that with a warming climate, most eco-zones or species distributions have and will continue to gradually migrate northward, where there is the land or water needed by the species (Soja et al. 2007; Bellard et al. 2012). The adaptability of species to changes in ecosystem functions will vary among species, with some better able to adapt than others. Muskox and caribou (woodland and barren ground), for example, are sensitive to changes in forage and to the changes in the intensity of insect harassment, both of which affect feeding, animal condition, and subsequent reproduction and recruitment.

In the marine ecosystems, seals, walrus, narwhal, beluga, and polar bear are widely found throughout the Canadian Arctic and are commonly harvested by Inuit. Species, such as seals, dependent on sea ice as a platform for resting, pupping, molting, and feeding are already showing stress in their southern limit as ice conditions change. Earlier ice breakup and reductions in snow depth have affected ring seal survival and recruitment (Harwood et al. 2000; Loeng 2005). Species that rely on the ice-edge environment, such as beluga, narwhal, and walrus, are particularly vulnerable to the effects of projected decreases in sea ice cover (Loeng 2005).

The distribution of polar bears is largely a function of sea ice conditions that allow them to effectively hunt and reproduce. Ringed seals are an important food source for polar bears and hence the changes in ice conditions that affect ring seal populations directly affect polar bears. There is evidence of significant declines in the numbers and condition of polar bear populations in their southern range, notably in western Hudson Bay, and these trends are projected to continue (Stirling and Parkinson 2006; Hunter et al. 2010).

Inuit lives and livelihoods are closely dependent on these physical and biological systems. Inuit have identified changes in conditions that affect them and are already adapting to vulnerabilities associated with climate change.

4.23.3 Vulnerability and Adaptation

There is a strong international scientific consensus that climate change is already underway in the Arctic (ACIA 2005; IPCC 2007a). The main response of governments to concerns over climate change has been to seek reductions in greenhouse gas emissions to 'mitigate' changes to the climate system (UNFCCC 2002). While mitigation is clearly needed, even with the most aggressive control measures, current greenhouse gas emissions commit the Earth to some degree of climate change, requiring nations, regions, communities, and individuals to undergo some level of adaptation (Klein et al. 2005; Hare and Meinshausen 2006; Rogelj et al. 2010). Adaptation is particularly important in the Arctic where climate change is already affecting local ecosystems and livelihoods. Adaptation in the context of human dimensions of climate change refers to an adjustment in human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities (Smit et al. 1999). Adaptation is expected to address areas in which communities are vulnerable to climate change.

Several approaches have been employed to assess the implications of possible changes in climatic conditions in the Arctic and associated opportunities for adaptation. Research on climate impacts has been focusing on modeling future climate change scenarios, their physical effects, and the implications of hypothetical adaptations (IPCC 2001). Referred to as the 'climate impact approach' or the 'scenario-based approach,' these top–down studies have been conducted at large scales, and focused on long-term changes in average climate conditions (variables most readily available from climate models) for the main purpose of quantifying the net impact of climate change (Brooks 2003). Due to these limitations, a broader approach to adaptation needs to be adopted.

Adaptation, if addressed at all, has up to now focused on assuming the adoption of hypothetical technical measures (Klein et al. 1999). The climate impact approach has improved our understanding of the potential severity of future climate change impacts, but has not explicitly addressed adaptation processes (Jones and Boer 2003). Recognizing this deficiency in knowledge and understanding of adaptation, recent adaptation research has drawn on theory from social vulnerability (e.g., Sen 1981; Bohle et al. 1994; Adger 2003) and work in human ecology of natural hazards and risk management (e.g., Blaikie and Brookfield 1987; Blaikie et al. 1994; Cutter 1996), to develop an integrated understanding of vulnerability.

To initiate adaptation, decision makers need to know the nature of vulnerability, in terms of who and what (e.g., economy, food security, infrastructure, etc.) are vulnerable, to what stresses, and in what way, and also what is the capacity of the system to adapt to changing conditions (Smit et al. 2000; Turner et al. 2003; Schroter et al. 2005). In the climate change field, the term vulnerability refers to the susceptibility of a system (community) to harm relative to a climate stimulus or stimuli, and relates to the exposure-sensitivity of the community to a climate stimulus and the capacity to adapt (Smit and Wandel 2006). Beyond the climate change impact research, studies have built on the natural hazards field to focus on the social dimensions of human sensitivity and adaptability, and have considered vulnerability to climate change in the context of the other economic, social, cultural, and environmental forces that affect communities (Adger et al. 2001; Kasperson and Kasperson 2001; Cutter et al. 2003; Turner et al. 2003). It is also accepted that adaptation initiatives are most effective when they are integrated, or mainstreamed, into other resource management, disaster preparedness, and/or community planning programs and institutions (Burton et al. 2002; Ford et al. 2007; Huq et al. 2004; Klein et al. 2007). This integration requires active involvement and collaboration with community members, and knowledge of local institutions and policies and the forces that influence vulnerability. A research approach that captures these needs and is recognized by the ACIA (2005) and IPCC (2007b) is the 'vulnerability approach.'

The vulnerability approach seeks to describe the processes and forces that influence and structure vulnerabilities in particular places to help identify why vulnerability exists and to identify opportunities for adaptation (Smit et al. 2010). The approach first assesses current vulnerability by documenting how people are exposed and sensitive to climatic variables, and the adaptive strategies they employ to deal with these conditions. Then future vulnerability is estimated relative to current conditions and future climate possibilities and future social trends (Ford and Smit 2004). Exposure-sensitivity refers to the susceptibility of people and communities to variable conditions, and adaptive capacity refers to the potential of a community to adjust in order to deal with plausible changes (Smit and Wandel 2006). In order to document vulnerabilities, it is necessary to gain insights on the experiences of people and their livelihoods and institutions. As such, a key feature of this vulnerability approach is its engagement with the community as the first source of information, to identify the conditions that are pertinent to the community, and to document adaptive strategies actually employed. Hence this approach is sometimes called 'bottom–up' or 'starting point' in the climate change field.

4.23.4 The Canadian Arctic and Community Vulnerability Studies

The Canadian Arctic is divided into four Inuit regions as settled by comprehensive land claim agreements and together Inuit settlement regions cover 31% of the Canadian landmass (Table 1). There are approximately 50 000 Inuit living in the Canadian, with over half living in Nunavut and the other half dispersed across the other three settlement areas. The climate of the Canadian Arctic is characterized by seasonal extremes, cold, long winters and short, cool summers, with the majority of the land surface area composed of continuous permafrost. Sea ice is an important part of Inuit livelihoods and depending on the geographic location, the length of time that

the ocean is frozen varies from approximately 7 months to nearly year-long coverage. Inuit use the sea ice for hunting marine wildlife and for traveling to hunting grounds and to other communities.

Most Inuit live in small, remote, coastal communities, with economies composed of wage employment and subsistence hunting. Prior to settling in communities, Inuit were semi-nomadic and traveled on the land, following wildlife and seasonal patterns. The wage economy in most arctic communities is based on public administration, arts and crafts, tourism, and increasingly on resource extraction. Despite undergoing sweeping political, social, and economic changes in the past half-century, subsistence hunting, fishing, and trapping continue to be important in the lives of many Inuit, and country foods (locally harvested fish and wildlife) are the main source of meat for many households. However, settlement in communities and associated changes have also stressed Inuit society and communities are challenged by limited access to health care services, low socioeconomic status, high unemployment, poor quality housing, concerns regarding basic services such as drinking water quality and sanitation, and low educational achievement (AHDR 2004; Furgal and Prowse 2008). It is within this context that Inuit communities experience and respond to climate, with socioeconomic and political conditions influencing how communities are affected by climate and their capacity to adapt.

Studies of Inuit perceptions of change and vulnerability to change have been undertaken in a range of communities across the Canadian Arctic (**Figure 1**). This chapter draws mainly on published community-based studies of vulnerability to climate change including Tuktoyaktuk, Ulukhaktok, Sachs Harbour, Inuvik, Aklavik, and Paulatuk in the Inuvialuit Settlement Region (ISR); Igloolik, Arctic Bay, Clyde River, Cape Dorset, Iqaluit, and Kugluktuk in Nunavut; Akulivik, Kangiqsualujjuaq, and Kuujjuaq in Nunavik; and Nain in Nunatsiavut (Berkes and Jolly 2002; Ford et al. 2006a, Ford et al. 2006b; Furgal and Sequin 2006; Gearheard et al. 2006; Tremblay et al. 2008; Ford and Beaumier 2010; Friendship and Community of Aklavik 2011; Pearce et al. 2010; Pearce et al. 2011; Prno et al. 2011; Andrachuk and Smit 2012; Pearce et al. 2012). Although the susceptibilities to changing conditions are distinct to each community, because both the exposure-sensitivities and adaptive strategies are place specific, there are some broad types of vulnerability that are evident across the Canadian Arctic (**Table 2**).

Each type of vulnerability represents an aspect of community susceptibility; however, they are not discrete, but rather are interrelated – for example conditions that influence hunting are also relevant to transportation, culture and learning, and health and well-being. In the following sections, each of these types of vulnerability is outlined, with illustrative examples from selected communities.

Table 2 Main types of vulnerability in Canadian Arctic communities

Vulnerability types	*Common elements*
Subsistence hunting	Increased travel risks; access to hunting grounds; quality and availability of wildlife
Transportation	Compromised trail routes to hunting grounds
Infrastructure	Permafrost degradation affecting buildings; coastal erosion
Health and well-being	Food security – access, availability, quality
Culture and learning	Erosion of environmental knowledge and land skills among young Inuit
Business and economy	New shipping opportunities; compromised ice roads; negative consequences for sport hunting industry (local guides and outfitter; local businesses)

4.23.5 Subsistence Hunting

Harvesting fish and wildlife for food and income is a long established and highly regarded feature of Inuit society. In the context of subsistence hunting, changes in temperature and seasonality, shifts in sea ice and wind dynamics, and weather patterns exacerbate risks associated with hunting and travel, and affect the health and availability of some species of wildlife important for subsistence. Traveling on the land, water, and sea ice is inherently dangerous and Inuit have long known about and coped with these risks. However, in recent years, changes in climatic conditions have altered, and in some cases increased, the magnitude and frequency of hazards with which people have to deal. In particular, hunters are increasingly exposed to hazards associated with more variable and less predictable weather: the weather changes quickly with minimal warning, and it is difficult to forecast wind direction and the development of storms. For example, Pearce et al. (2010) documented in Ulukhaktok, Northwest Territories (NWT), that less predictable weather, stronger winds, and severe storms are making travel and hunting more difficult, if not impossible, and increasingly hazardous. 'White-out' conditions reduce visibility and travelers have been separated from their travel patterns, lost, stranded, and have encountered hazards such as driving their snow machines into rocks or over cliffs, a hazard that would be avoided in better visibility. Hunters explain that they are unable to read signs in the weather like they used to because the weather and seasonal changes no longer follow regular patterns (Pearce et al. 2010).

In the marine environment, hunters are increasingly faced with risks associated with changing sea ice conditions. Some areas of sea ice, over which hunters are accustomed to travel, are no longer stable and in some instances the ice is not forming or does not form in a manner consistent with their experiences (Ford et al. 2006a,b; Pearce et al. 2010). Unstable ice conditions, together with greater variability and less predictable weather, are making it difficult for hunters to identify when it is safe to travel. There have been several cases of hunters being stranded and/or injured due to rapidly changing ice conditions, sometimes requiring assistance from federal search and rescue efforts. For example, in Igloolik, Nunavut sudden and rapid changes in the wind and consequently sea ice dynamics have stranded walrus hunters on moving pack ice, and resulted in the loss of hunting equipment (Ford et al. 2006a).

Inuit hunters are adapting to the enhanced risks associated with changing climatic conditions by taking extra precautions before and during travel. Hunters are taking extra time to read environmental signs and weather forecasts before traveling. This may include consulting elders and/or other experienced hunters to determine whether conditions are safe for travel and also satellite imagery of the sea ice and weather forecasts. Hunters are packing extra gas, heating fuel, food, and supplies in the event that they become stranded on the land. During times of the year when conditions are most precarious (e.g., late fall and early spring), some hunters are choosing to travel closer to the community and by established trail routes. Hunters are also more often traveling in groups, and are carrying VHF radios and satellite phones to maintain communication with people in the community. Some analyses of climate change impacts have suggested that the gradual retreat of sea ice extent would be a problem for Inuit hunters. Evidence on the ground indicates that hunters can readily adapt to such changes in ice extent (e.g., by not having to travel such long distances to the floe edge for hunting), but they are challenged more by changes in the stability of the ice over which they travel and by changes in the abundance, location, and condition of species they hunt.

Changes have been documented in the health and availability of some species of wildlife important for subsistence with possible links to climate change (Nancarrow and Chan 2010; Regehr et al. 2010). A study of the ringed seal population in the Beaufort Sea documented that even a very local, small-scale, premature disruption of the landfast breeding habitat has significant negative impacts on the growth, condition, and survival of unweaned pups (Harwood et al. 2000). Warmer temperatures in spring have caused seal birth lairs to melt earlier, exposing pups at earlier ages to predation and freeze–thaw cycles. As ringed seals are the primary prey of polar bears, a decline in ringed seal populations, especially in birth rate, is capable of having negative effects on the health of polar bears (Stirling and Parkinson 2006). Inuit across the Canadian Arctic hunt polar bear for subsistence and as a source of income. There are differing perspectives on the links between polar bear health and climate change most likely the result of climate change impacts being spatially uneven; some polar bear populations may be negatively affected by changing ice conditions, whereas other may not be. For example, scientists studying a population of polar bear in Hudson Bay have documented a significant positive relationship between the timing of sea ice breakup and the body condition of adult female polar bears (the earlier the ice breakup, the poorer the body condition of the bears) (Stirling et al. 1999, Stirling and Parkinson 2006). Later sea ice freeze-up and earlier breakup have also been linked to reduced reproductive rates in the same population of bears (Derocher et al. 2004).

Inuit have demonstrated strong adaptability to changes in the availability of wildlife species important for subsistence.

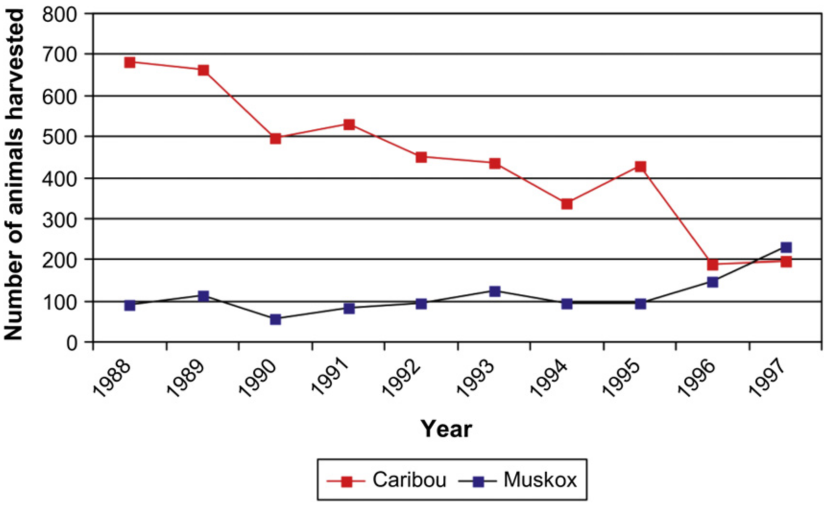

Figure 2 Number of caribou and muskox harvested by hunters in Ulukhaktok, Northwest Territories between the years 1988 and 1997. Source: IHS, 2003: *Inuvialuit Harvesters Study: Data and Methods Report, 1988–1997*. Inuvialuit Joint Secretariat. 202 pp.

When one species of wildlife is less abundant, Inuit shift to harvest another species of wildlife, an adaptation that has been possible due to the diversity of wildlife available in the Arctic environment. For example, beginning in the late 1970s, there was a dramatic decline in the Peary caribou population on the Arctic islands, a primary source of meat for many Inuit. A possible cause for this decline in caribou is the increase in freeze–thaw events, which has resulted in ice layers developing in the snow pack and hinders the ability of caribou to travel and forage for food (Russel 2007). In 1993, the community of Ulukhaktok implemented a voluntary moratorium on hunting Peary caribou and was able to supplement muskox for the lost caribou meat (Figure 2).

4.23.6 Transportation

Changing snow and ice regimes, less predictable weather, and changing wind patterns are increasing dangers for travelers, making semipermanent trails for hunting and recreational travel less dependable, and compromising the ability to engage in harvesting activities (Aporta and Higgs 2005; Ford et al. 2006a, 2006b; Tremblay et al. 2008; Pearce et al. 2010). Travel risks are especially pronounced during fall freeze-up, with warming and more variable temperatures prolonging the period of ice instability, and during spring melt, with less predictable snow and ice regimes.

The spring is a popular time for Inuit to travel on the land to ice fish at lakes and to hunt terrestrial wildlife (e.g., muskox, caribou), and on the sea ice to hunt marine wildlife (e.g., seals, whales, walrus, polar bear). However, in recent years changes in the timing and nature of the spring melt have resulted in earlier and more rapid melting of snow and ice, which has made travel by snow machine more difficult, dangerous, and sometimes impossible. An Inuit elder from Ulukhaktok, a small settlement located in the western Canadian Arctic, explained that in the years that he has been traveling on the land the spring melt usually started in May and June and the snow would melt gradually from the top down. In recent years, however, the melting has started from underneath the surface of the snow, and although snow conditions appear to be good for traveling, they are not because there is so much moisture and water under the snow that snow machines sink and become stuck in the moist ground (Pearce et al. 2010). Rapid periods of melting have also caused rivers and lakes to thaw earlier, which has affected travel routes and sometimes blocked travelers from being able to return to the community. These local observations and knowledge are consistent with instrumental measurements of the spring melt in the western Canadian Arctic. An increase in the number of days with thaw defined as a day with snow on the ground when the daily mean temperature is above $-2\,^{\circ}\mathrm{C}$ (Brown 2000) has been recorded over the past 50 years (Smith 1998; Callaghan et al. 2011).

Inuit are adapting to changing trail conditions by altering the timing and location of hunting activities, switching species harvested, using new travel routes, and avoiding travel at certain times and locations (Furgal and Seguin 2006, Gearheard et al. 2006, Ford et al. 2008, Tremblay et al. 2008). For example, in the event of an early sea ice breakup or late freeze-up (when travel on the sea ice is not feasible), hunters who have access to alternative modes of transportation have adapted by traveling to hunting areas by all-terrain vehicle (ATV) or boat. Several factors underpin these adaptive responses including, but not limited to, access to alternative modes of transportation, availability of alternative species of wildlife to hunt, and traditional knowledge and land skills, which enable hunters to travel in unfamiliar locations.

4.23.7 Infrastructure

Across the Arctic, thawing permafrost, changes in the coastal zone, and extreme weather events have damaged buildings, roadways, airports, and utilities (Instanes 2005). The sensitivity of built infrastructure (e.g., roads, buildings, utilities, airports), however, varies depending on the geography of the community. For example, communities located in the Mackenzie Delta in the western Canadian Arctic are particularly sensitive to permafrost thaw due to their construction on ice-rich flood plains (Hoeve et al. 2006). Coastal erosion, flooding, and warming in 'shoulder seasons' (i.e., fall freeze-up, spring melt) has also affected the integrity of buildings, services, and winter road networks.

The Inuvialuit settlement of Tuktoyaktuk provides an illustration of the vulnerability of infrastructure to climate change (Andrachuk and Smit 2012). Buildings and other infrastructure in Tuktoyaktuk are highly susceptible to damage due to permafrost degradation and coastal erosion. The mainland coast of the Beaufort Sea is characteristically prone to erosion, with average retreat rates in some areas of 1 m year^{-1} (Carmack and MacDonald 2002). The shorelines of the community itself are known to have eroded on average 1 to 2 m year^{-1}, but erosion of several meters has occurred during individual storms (Couture et al. 2002; Solomon et al. 1993). Climate change is generally considered to exacerbate shoreline erosion. It is thought that since sea ice provides protection for shorelines by suppressing the development of waves, longer open water seasons (and thus greater fetch distances for wave buildup) are enabling greater rates of erosion (Manson and Solomon 2007). The key conditions are high-energy storm events. Average daily energy acting upon shorelines has a relatively small impact on shorelines compared to strong storm events that can cause considerable change in relatively short periods of time, especially with winds blowing from the northwest, which leads to the most direct exposure. Such events of rapid coastal retreat tend to occur in late August and September in Tuktoyaktuk when strong storm events are more frequent. This is also the time when later freeze-up leaves the shorelines less protected by ice. Shoreline protection measures were initiated in the 1970s and have moderated shoreline erosion along parts of the coast; however, these efforts have not been successful in stopping all erosion, and it is questionable whether they will be able to withstand changes associated with some of the plausible changes in the region's climatic conditions.

4.23.8 Health and Well-Being

The effects of climate change on subsistence hunting have implications for Inuit food security, which concerns the ability of individuals and households to reliably access food of an acceptable quality. Three components of food security – access, availability, and quality – are particularly sensitive to climate change. In some instances, the connection between climate change and food security is direct. For example, as described in the previous section, changing sea ice conditions are affecting the ability of hunters to access hunting grounds. Furthermore, changes in the health and availability of some species of wildlife affect the success of hunts and the quality of some meat. In other instances, the link is indirect where food security is affected by the increased economic burden of hunting imposed by changing climate conditions. For example, if trails on the sea ice are unstable and hunters are required to travel by ATV or boat to access hunting grounds, only hunters with access to these modes of transportation are able to continue to hunt and this may result in some households acquiring less country food.

Inuit have historically responded to changes in access to country foods by distributing food through traditional sharing networks. Food sharing provides community members with country foods despite their ability to engage in subsistence, including those whose access to country foods is inhibited by changing climatic conditions. Food sharing is also part of a greater emotional and social bond that is built among individuals and which is important for a healthy community.

4.23.9 Culture and Learning

The ability of Inuit to adapt to climatic changes that affect subsistence hunting is influenced by the level of knowledge one has of the Arctic environment, which affords some Inuit dynamic and flexible use of the land and its resources. Traditionally, hunters managed risk by careful planning and preparation, bringing the right equipment, taking precautions, and by noting critical signs in the environment and responding appropriately. Knowledge of animal behavior enabled them to adapt to changing animal numbers and location, while knowledge of the land underpins the ability to do this. Traditionally, environmental knowledge and land skills were transmitted between generations through practical engagement with the environment. However, younger Inuit are spending considerably less time engaged in subsistence activities beyond organized land-camps and occasional hunting trips, but more time in formal education and wage employment. As a result, many younger and inexperienced hunters are not as well equipped to cope with the risks of hunting. More than a few young Inuit have encountered hazards and some have been seriously injured because of their poor understanding of dangers on the land. Changing climatic conditions are making it even more dangerous for them.

There is an expressed need among Inuit and northern educators for educational programming that supports the teaching and transmission of environmental knowledge and land skills in order to strengthen the competence of young Inuit, and therefore Inuit capacity to adapt to changing climatic conditions. Some communities are facilitating land-camps, led by elders and experienced hunters, to help engage youth who may otherwise not have the opportunity, in subsistence activities. In other cases, land skills such as navigation and wayfinding, and basic hunting and meat preparation skills are being taught in the school and applied during school-organized hunting trips. In Nunavut, an Inuit cultural school, Piqqusilirivvik, is being developed in Clyde River and is an attempt to integrate Inuit traditional modes of learning into a formal education setting. Initiatives to support the teaching of environmental knowledge and land skills, while not directed at climate change adaptation specifically, will indirectly prepare Inuit to deal with and adapt to climatic changes that affect subsistence.

4.23.10 Business and Economy

Most Inuit living in the Canadian Arctic live in small remote settlements that are accessible by air year round and by boat in the ice-free open water period of the summer. The economies of most communities are a mix of wage employment, administration, municipal services, arts and crafts, tourism, and subsistence. Climate change presents both risks and new opportunities for northern economies. Mining development is expanding rapidly in the Canadian Arctic, aided by reduced sea ice cover in summer months, which is improving shipping access and may continue to improve in the future (Stroeve et al. 2008). Changing sea ice regimes are also increasing opportunities for cruise-ship tourism, which presents potential income-generating opportunities for communities on the ship's path. However, climate change also presents a number of challenges for economic development in the north. For example, in the western Canadian Arctic, the viability of seasonal ice roads to diamond mining operations have been compromised due to warming winter temperatures and early spring melts (Pearce et al. 2010). The listing of polar bears as a 'vulnerable species' due to climate change under the U.S. Endangered Species Act in 2008, and subsequent ban on the importation of polar bear products to the United States, has also had negative economic consequences for Inuit communities, who once relied on American sport hunters for their income (Freeman and Wenzel 2006; Dowsley 2009).

4.23.11 Conclusions

Among the most compelling manifestations of climate change are those occurring in the Arctic: shrinking sea ice, melting permafrost, and threats to terrestrial and marine biota. Humans in the Arctic, notably the indigenous populations, are particularly dependent on the natural environment, and hence are vulnerable to climate-related changes in the cryosphere and hydrologic systems, and to shifts in animal populations. The human dimension of the Arctic ecosystem is experiencing the effects of a changing regional climate, and is adapting to these new conditions at the same time as it is dealing with a range of social, cultural, and economic pressures from outside.

Among the Inuit of the Canadian Arctic, notwithstanding differences from region-to-region and community-to-community, there are several commonly recurring vulnerabilities. Subsistence hunting is important for food, culture, and income, and is susceptible to changes in wildlife populations and access to hunting areas. Transportation is becoming problematic as trail routes are compromised by changes in the stability of ice. Permafrost degradation has implications for community infrastructure and for coastal erosion. Changes in the availability of harvested food contribute an additional risk to people's health. Also the erosion of environmental knowledge and land skills enhances the vulnerability of Inuit culture. Economic opportunities may come with more shipping, but may be constrained by closed ice roads and limits on the sport hunting industry.

Inuit pride themselves on their adaptability. They have had to adapt to some of the most severe environmental conditions known to humankind, and they have demonstrated considerable resilience in the face of changes already experienced. Given that climate change is expected to continue and accelerate, the question arises: how far and in what areas can the resilience of Inuit stretch? There are certainly opportunities to enhance the capacity to adapt to changing climate conditions, but this capacity clearly has some significant constraints. Constraints to Inuit adaptation include, but are not limited to, changing levels of traditional knowledge and skills among younger generation Inuit; high costs of hunting; limited financial resources (few wage jobs, lack of qualifications, nepotism); substance abuse (sapping material resources and impairing decision making); infrastructure not well-adapted to a changing climate; reduced resource-use flexibility due to harvesting seasons and quotas; and constraints due to the nature of some community locations (e.g., access to wildlife species; susceptibility of infrastructure to harm due to local geography – permafrost, coastal erosion). Constraints to adaptation, however, represent strategic policy entry points in which to enhance adaptive capacity now and in the future. Supporting efforts that increase financial, health, educational (e.g., supporting the teaching of environmental knowledge and land skills), institutional (e.g., flexible wildlife management regimes), and cultural capacity will inadvertently enhance the adaptive capacity of Inuit to deal with current and expected future climate change risks.

Photo 1: Taking extra precautions when traveling on the land and ice

Subject in photo: Roland Notaina and Joseph Kuptana, Ulukhaktok, Northwest Territories, Canada
Date: March 2009
Location: On the land near Ulukhaktok
Inuit hunters, Joseph Kuptana and Roland Notaina, secure supplies in their aalliaks (sled) during a hunting trip for omingmak (muskox). Hunters in Ulukhaktok are increasingly taking extra precautions when traveling, including traveling with extra fuel and supplies and carrying VHF radios and GPS, to avoid and/or be prepared to cope with emerging risks.

Photo 2: Changing sea ice conditions

Subject in photo: Adam Kolouhok Kudlak, Ulukhaktok, Northwest Territories, Canada
Date: 20 February 2009
Location: Open water lead (aolagot) near Holman Island (Qikiktakyoak)
Inuit travel on the sea ice to access hunting grounds. Arctic sea ice extent and volume, however, have been declining rapidly, compromising travel routes and creating new hazards for hunters.

Photo 3: Muskox

Subject in photo: Muskox
Date: March 2010
Location: On the land near Ulukhaktok.
Muskox are hunted by Inuit for their meat and hides, which are valued for their kiviut (wool). When there was a decline in the Peary caribou population, Inuit in Ulukhaktok switched to harvesting more muskox, demonstrating flexibility in harvesting techniques and dietary needs.

Photo 4: Tuktoyaktuk shoreline

Date: August 2007
Location: Tuktoyaktuk
Buildings and other infrastructure in Tuktoyaktuk are highly susceptible to damage due to permafrost degradation and coastal erosion.

4.24.1 Introduction

Over the latter half of the twentieth century, tourism grew rapidly into a global economic and social phenomenon. Despite multiple economic, environmental, social, and political challenges and occasional major shocks – from recessions to terrorism to disease epidemics – the last six decades have seen extraordinary growth in international tourism, as well as domestic tourism in many nations. From 1950 to 2005, international arrivals increased by 6.5% per year, from an estimated 25 million in 1950 to 940 million in 2010 (United Nations World Tourism Organization (UNTWO) 2011). Tourism contributes directly to between 5 and 9.6% of the world's GDP and an estimated 8% of worldwide employment (World Travel and Tourism Council 2009). The next two decades are anticipated to see sustained growth in the tourism sector, though at a slightly slower pace than previous decades, with international leisure and business arrivals reaching 1.8×10^9 in 2030 and four times as many tourists traveling domestically (UNWTO 2011).

Tourism development has been and will continue to be influenced by many macro-scale factors, including economic growth, demographic change in industrialized and developing countries, increased travel safety and health concerns, social trends, environmental and cultural awareness, advances in communication and information technologies, environmental conditions (including climate), and transportation access and speed. It is important to recognize that specific tourism destinations and market segments are differentially sensitive to changes in and interactions between these macro-scale factors.

Tourism has been recognized as a highly climate sensitive sector since the 1970s (Maunder 1970; Perry 1972). A more recent World Meteorological Organization White Paper (Scott and Lemieux 2010) outlined the multifaceted and complex interface between weather, climate and tourists, tourism operators, and destinations. Weather and climate have broad significance to tourist decision-making and the travel experience. Climate, both at home and at a destination, is a salient motivator for many tourists and a key factor considered, either consciously or implicitly, in destination choice. Destination weather is an intrinsic component of the travel experience and has been shown to influence tourist activity choices and expenditures, as well as overall trip satisfaction.

Weather affects tourism operators in several ways (e.g., investment and locational analysis, infrastructure design, operational decisions and budgeting, risk assessment, and marketing) and over a wide range of timescales. Interannual weather variability defines the length and quality of multibillion dollar tourism seasons in different parts of the world. Extreme weather and climate-related environmental events also routinely have major impacts on tourism operators, particularly those located in highly dynamic environments like coastal areas, mountains, or fire-prone forests.

Weather and climate are also salient for tourism destinations, influencing their short- or long-term competitiveness and sustainability in diverse ways. All tourism destinations are affected either positively or negatively by natural seasonality in travel demand; interannual weather variability that can bring unseasonable temperatures or substantial fluctuations in precipitation causing drought, flooding, or transportation interruptions, and extreme events that not only affect tourist comfort and safety (and thereby satisfaction), but also the products that attract tourists and tourism infrastructure. Climate has universal importance in defining destination attractiveness and is used extensively in marketing, often with an obvious 'blue sky' bias.

The natural environment, personal safety, travel costs, and accessibility are the primary factors that affect travel decisions and the success of tourism. Because each of these factors can be highly impacted by regional climate and climate policy (Gössling and Hall 2006; Scott et al. 2008; Becken and Hay 2007), climate is considered a pivotal issue for medium and long-term future tourism development. Tourism is also considered to be one of the major global economic sectors that are currently the least prepared to deal with possible changes in climate (KPMG 2008).

Specific types of tourism destinations and market segments are differentially sensitive to climate and environmental change, with mountain destinations and winter sports tourism considered being particularly sensitive. After coasts and islands, mountains are considered the most important destinations for global tourism. Tourism is of great economic importance to many mountain communities and is one of the fastest-growing economic sectors for mountain regions of the world (Godde et al. 2000). Mountain ecosystems are among the most vulnerable to environmental change (Beniston 2000; Parry

http://dx.doi.org/10.1016/B978-0-12-384703-4.00440-8

et al. 2007), with possible retreat of alpine glaciers and changes in ecosystem composition and distribution potentially reshaping natural and cultural alpine landscapes in the decades ahead. A number of authors have warned of the potential negative effects of landscape change for mountain tourism (Wall 1992; Elsasser and Bürki 2002; Nyaupane and Chhetri 2009), though empirical analysis of potential tourist response remains rather limited (see Richardson and Loomis 2004; Scott et al. 2007a).

With its very visible sensitivity to variability in snowfall, winter sports tourism, and in particular the ski industry, has been repeatedly identified as highly vulnerable to changes in temperature and precipitation. Media prognostications in Europe, the United States, Canada, and Australia have declared climate changes could 'wipe out' large portions of the ski industry and discussed where it is safe to buy ski resort property, in order to avoid devastating future losses in real estate value. The CEO of Aspen Resorts has stated that "Climate change is the single biggest threat facing our business…" (Aspen Ski Company 2009). However, others have a very different perspective and remain largely unconcerned, at least publicly, about their capacity to cope with any future climatic conditions.

This chapter examines these differing perspectives on the climate vulnerability of the multi-billion dollar global ski tourism industry. Section 4.24.2 outlines the economic importance of ski tourism to mountain regions around the world and recent regional trends in visitation. Section 4.24.3 examines the evolution of the ski industry's climate sensitivity over the last three decades, and the adaptations that made this possible. The large literature on the climate vulnerability of the ski industry is then critically examined and the implications for future policy relevant research discussed in Section 4.24.4. In Section 4.24.4.1, a new sensitivity analysis framework is introduced to facilitate comparisons among future climate assessments in this sector. Recommendations for policy makers and ski industry stakeholders (see Section 4.24.5) conclude the chapter.

4.24.2 The Winter Sports Tourism Industry

While it is difficult to compare the economic size of the ski industry around the world because of the differences in the way ski industry is structured (single or multiple owners of ski lifts, on mountain restaurants and accommodations, ski schools, retail operations, etc.), and the quality of data, direct revenues by the global ski industry exceed US$9 billion each year. In the US, members of the National Ski Areas Association (NSAA) had direct revenues (not including real estate sales) of over US$3 billion in 2010–11 (IBIS World 2011). Ski areas in Canada reported revenues of approximately US$900 million in 2009 (Statistics Canada 2009), while a similar economic significance was reported for Australian alpine resorts in 2005 (Alpine Resorts Coordinating Council 2006). Decade old estimates by Lazard (2002) show the ski industry in Western Europe and Japan had annual revenues of over US$3 billion and US$1.4 billion, respectively.

The ski industry is considered a relatively mature tourism market, and while growth in the number of ski areas and skiers has continued in emerging markets (China, Southern America, Eastern Europe), in the major markets of North America, Europe, and Japan, the number of operating ski areas and ski participation has declined in the last decade. The United States has some of the best longitudinal data on the ski industry and this marketplace can be considered a reasonable proxy for the impact of economic and demographic trends on the ski industry in Canada, Western Europe, and Japan. In the United States, skier visits reached a new record in 2010–11 at 60.5 million, up from 57.4 in 2000–01 and 46.7 in 1990–91 (NSAA 2011). While positive, these figures do not reveal the demographic challenges the ski industry is facing. Ski participation surveys of the US population showed a different trend, with a decrease in the number of skiers–snowboarders from 12.9 million in 1990 to 11.6 million in 2006 (National Ski and Snowboard Retailers Association 2006). The average age of active skiers in the United States also continues to rise, from 33 in 1997–98 to 37 in 2006–07 (NSAA 2008). Similar trends have occurred in Austria, where skier surveys showed a decrease of young skiers (<30 years) from 29% in 1991 to 16% in 2007, and simultaneously an increase of skiers in the 50 years and older age group from 26 to 35% (Steiger 2012). These demographic trends and recent economic recessions and forecasts of limited economic growth over the next 10–15 years present important challenges to ski tourism demand in the US and other mature ski tourism markets.

How the impacts of salient long-term demographic and climatic drivers of the winter tourism sector will interact to influence ski tourism supply and demand remains an important uncertainty (Scott 2006).

4.24.3 Evolution of Ski Industry Climate Sensitivity

As the ski industry evolved throughout the twentieth century, the number of operating ski areas peaked in the 1970s and has gradually declined as many smaller ski areas closed, because of tremendous changes in the marketplace that required much greater capital investment in larger and faster ski lifts, rental equipment and terrain grooming vehicles, snowmaking, resort accommodations and other tourism services (spas, retail stores, restaurants, and entertainment facilities), and real estate development (condominiums, time-shares, and other properties). These and other technological and business strategies lessened the sensitivity of ski businesses to interannual variability of weather conditions by reducing the variability in the length of ski season, increasing the capacity of ski areas to accommodate greater numbers of skiers at a time (e.g., operational intensity), and diversifying income sources to increase non-weather dependent revenues (Scott and McBoyle 2007).

These advancements have reduced climate sensitivity. For example, average season length increased from the 1980s to the 2000s in all five ski regions of the United States (109–126 days in the Northeast, 90–103 days in the Southeast, 95–100 days in the Midwest, 127–138 days in the Rocky Mountains, and 118–136 days in the Pacific West; **Figure 1**), even though average winter temperatures were warmer in the 2000s in all of these ski regions. The variability in season length also declined in the 2000s. Other analyses in Eastern Canada (Scott 2006), Austria (Steiger 2011a), and Italy (Steiger 2011b) have similarly found that the sensitivity of ski operations to anomalously warm winter conditions has declined since the 1980s. This

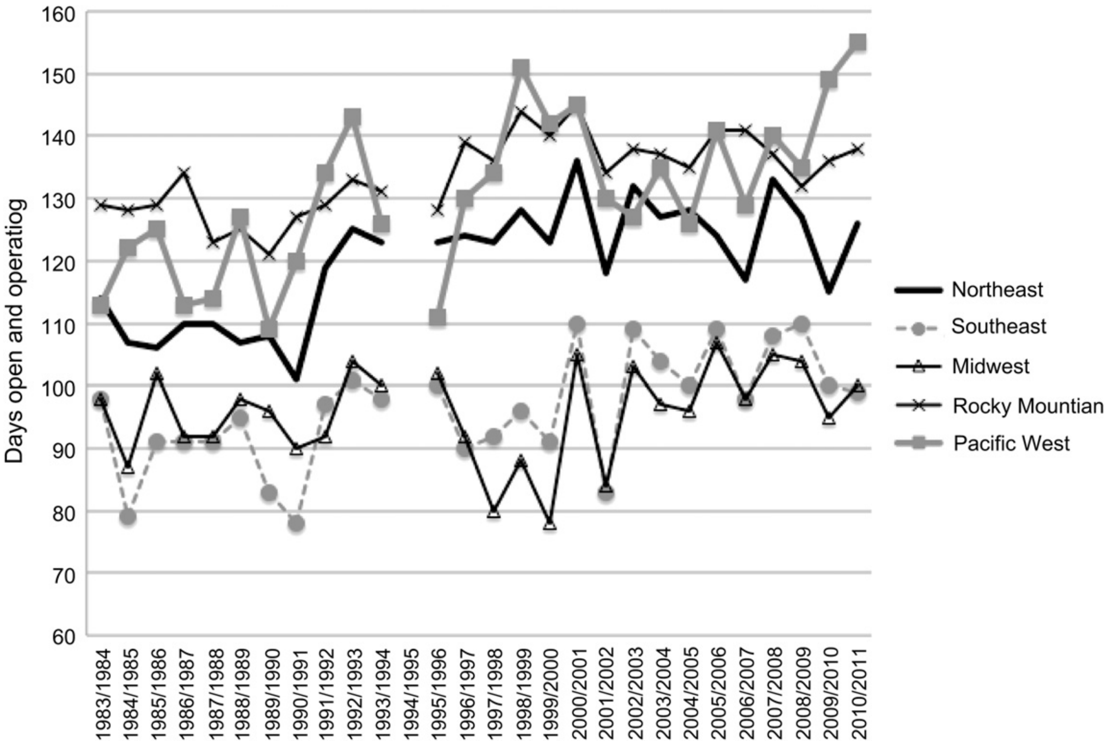

Figure 1 Ski season variability in US ski regions. Data source: National Ski Area Association – end of season survey reports 1983–2008

reduced climate sensitivity, including increased average season length and reliability of the ski season, particularly during winters characterized by high temperatures and low snowfalls, is directly attributable to the tremendous investments in snowmaking over the past two decades.

Snowmaking has become an integral climate adaptation in several major ski tourism regions. By the mid-1990s, more than 90% of ski areas in the lower elevation ski regions of the Northeast, Midwest, and Southeast had snowmaking capacity (Figure 2). Snowmaking is not as extensive in the higher elevation ski areas of the Rocky Mountains and Pacific Northwest regions, though it is used by the majority of ski areas in these regions at lower elevations. The proportion of skiable terrain covered by snowmaking in 2010–11 reveals the extent to which each of the ski regions rely on this technological adaptation: 74% in the Northeast, 98% in the Southeast, 82% in the Midwest, 13% in the Rocky Mountains, and 17% in the Pacific West. A similar east–west pattern exists in Canada (Scott 2006). In Australia, 100% snowmaking coverage is also common (Hennessy et al. 2008). In the European Alps, the proportion of skiable terrain with snowmaking is more similar to the higher elevation in the Western United States and Canada, but has expanded to over 70% in Italy, 65% in Austria, 36% in Switzerland, 21% in the French Alps, and 16% in Germany (CIPRA 2011).

It is important to note that while these adaptations to current climate provide the ski industry with some adaptive capacity in the decades ahead, the investments to reduce climate sensitivity over past three decades should not be construed as purposeful adaptations to some different future climate. Climate adaptations need to be capable of effectively dealing with all plausible future climate regimes and there is almost no evidence available that ski tourism operators have evaluated the design capabilities of their existing climate adaptations against the future range of climate possibilities. The following quote from a ski tourism operator in Tyrol, Austria, illustrates this difference very clearly (Trawöger 2011, p. 335):

> It would be presumptuous to say that the ski areas have taken precautions against climate change because we have not, we are not prepared. … Snow production may be a main strategy, but a strategy against a lack of snow, not against climate change. We have not taken any real precautionary measures against a marked warming trend yet.

4.24.4 Vulnerability to Climate

The climate vulnerability of the ski industry has been examined to some extent in 12 countries. These studies have consistently projected that the ski industry is at risk to decreased reliability of natural snow cover ('natural snow reliability'), shortened and more variable ski seasons, increased snowmaking requirements and decreasing snowmaking opportunities ('technical snow reliability'), and an overall contraction in the number of ski areas. The extent and timing of these impacts are highly uncertain, depending on the temperature and precipitation that actually occurs and whether the study accounted for snowmaking (see discussion below on the limitations of much of the extant literature).

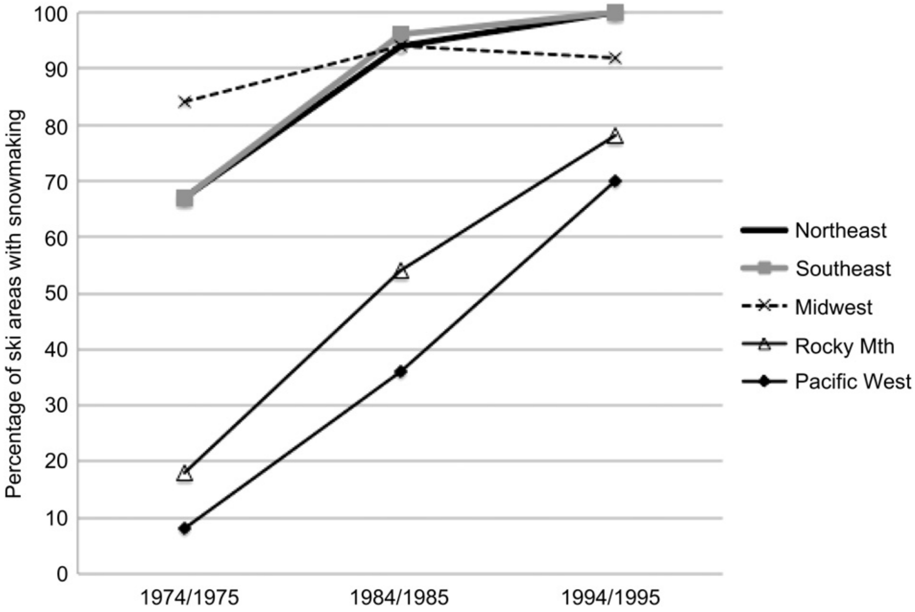

Figure 2 Diffusion of snowmaking capacity in the US ski industry. Data source: National Ski Area Association – end of season survey reports 1975–1995.

Climate assessments of the ski industry have utilized two main methodologies to estimate possible future changes in snow conditions and operational indicators (e.g., ski season length and snow reliable ski areas). Modeling-based analyses are the most common approach, and many of these studies suffer from two important limitations that reduce their validity and limit the relevance for decision makers. The use of inappropriate impact indicators is a first limitation. Some studies simply model natural snow conditions near ski areas without any specific indicators relevant to ski operations, such as the length of the ski season or opening – closing dates (e.g., Harrison et al. 1999; Uhlmann et al. 2009; Endler and Matzarakis 2011). Others utilize indicators that are not relevant to ski area operations, such as snow cover (which is a meteorological variable defined as 2.5 cm of snow, when ski operators require 30–100 cm of snow to open a ski run depending on terrain) (e.g., McBoyle et al. 1986; Lamothe and Periard 1988) or snow water equivalent on the first day of April (which is a widely used hydrological indicator for summer water supply in mountainous regions, but one that provides no insight into snow accumulation in the vital start of the ski season or the number of days with necessary operational snow depth) (e.g., Zimmerman et al. 2006). Yet others estimate ski season length solely on the basis of temperatures and rainfall, disregarding any measurement of snow depth and thus whether there is a snow product to ski on (e.g., Heo and Lee 2008). The second major limitation common too much of the literature, including the widely cited OECD analysis of the European Alps (Abegg et al. 2007) and all studies of the major ski regions in the western United States, has been the omission of snowmaking in regions where snowmaking is an integral adaptation to climate. Analyses that do not account for snowmaking, do not reflect the current operating realities of many ski operations, let alone their adaptive capacity 25 years from now, when studies have found most ski area managers plan to have enhanced snowmaking capabilities (Scott and Jones 2005; Wolfsegger et al. 2008; Hoffman et al. 2009), and consequently are of little use to the ski industry or policy makers.

State-of-the-art studies in Canada (Scott et al. 2003, 2007b), the United States (Scott et al. 2008), Australia (Hennessy et al. 2008), and Austria (Steiger 2010, Steiger and Abegg 2011) that have utilized physically based snow models to fully account for snowmaking as an adaptation have consistently found that the impact of warmer than current climate on ski areas was substantially lower than reported in studies that did not include snowmaking. However, in some regions, even with advanced snowmaking capacity, under the warmest mid-century scenarios, the ski tourism industry was found to be at risk of decreased reliability of natural snow cover ('natural snow reliability'), greatly increased snowmaking requirements and decreasing snowmaking opportunities ('technical snow reliability'), shortened and more variable ski seasons, and an eventual contraction in the number of ski areas. Lower elevation ski areas and the early portion of the ski season, including the economically important Christmas–New Year holiday period, were found to be at greater risk. Furthermore, the tremendous increase in snowmaking, particularly under warmer scenarios, necessitates greater examination of its sustainability in terms of costs and water and energy usage.

The second approach used to examine the impact of climate change on ski industry operations has been to examine the impact of anomalous climatic conditions, such as record warm winters or winters with limited or late snowfall, that could be analogs of possible future climate conditions. Analyses of recent record warm winters in North America (Scott 2006; Dawson et al. 2009) and the Tyrol region of Europe (Steiger 2011a,b) found ski seasons were shortened on average by only 4–10%, while snowmaking requirements increased. When examining the differential vulnerability of ski businesses, lower lying ski areas and smaller resorts consistently experienced the greatest loss in season length (Dawson et al. 2009; Steiger 2011a). Analog studies consistently found smaller losses in season length than modeling studies in the same regions. The differences can be explained by the inability of ski operations modeling to account for business decisions (e.g., opening under even very marginal conditions because of staffing inflexibility and to provide some level of skiing to guests staying in the resort), which can lead to the overestimation of season length losses. With improved cooperation of the ski industry, future analog studies could provide insight into the effectiveness of adaptive responses (from ski area operators, skier market segments, communities, and marketing organizations), identify key impact thresholds, and compare the relative vulnerability of different ski destinations.

The modeling and analog studies collectively reveal the differential vulnerability among ski areas and suggest that regional ski tourism markets have varied capacity to adapt to possible warmer conditions in the coming decades. However, the different snow modeling techniques, ski operations impact indicators, and climate scenarios used in the literature currently preclude accurate direct comparisons of the vulnerability of key ski tourism destinations or how regional ski markets are likely to evolve in response to future plausible climatic conditions. Such comparisons are necessary to assess the implications for tourism employment, real estate values, traffic congestion, development pressures (e.g., water requirements, access to higher terrain), and community and rural development planning.

4.24.4.1 Sensitivity Analysis

Here we introduce a new sensitivity analysis approach that utilizes industry relevant impact indicators (e.g., ski season length, snowmaking requirements) and the SkiSim2 ski operations model to facilitate inter-regional climate vulnerability comparisons across a wide range of potential climate futures. The diverse case studies of Vail (Colorado, USA) and Kitzbüehel (Austria) are used to illustrate the value of this comparative approach.

The SkiSim2 ski operations model uses a locally calibrated, physically determined snow model to simulate natural daily snow depth and snowmaking requirements for individual ski areas (across their full altitudinal range). See Steiger (2010) for more details on the development of SkiSim2 and the procedures to calibrate and validate the model for individual ski areas.

The model simulates the aim of ski area managers to maintain continuous operations between specified opening and closing dates (e.g., 1 Nov–31 March). Daily snowmaking occurs when the snow depth is insufficient for minimum specified operating conditions (e.g., 30 cm) and minimum temperatures required for efficient snowmaking are present (e.g., ≤ -5 °C). The maximum daily snowmaking output is also prescribed to represent that of advanced snowmaking systems (e.g., 10 cm day^{-1} over the skiable terrain covered by snowmaking). Snowmaking continues until a specified 'base layer' is established (e.g., typically 30–60 cm depending on terrain), which provides a dense snow base resistant to short mid-season melt periods and guarantees the planned season start. Further details on communications with the ski industry to establish key operational thresholds can be found in Scott et al. (2003) and Steiger (2010).

The climate stations used to represent the Vail and Kitzbüehel ski areas are presented in Table 1. The baseline winter climate at the two ski areas differs greatly. Although precipitation in the winter months is much higher at Kitzbüehel, snowfall and the number of snow days are much higher at Vail. This is attributed to the cold–dry continental climate of Vail versus the warm–humid climate of Kitzbüehel.

In Kitzbüehel, the ski season length modeled with the baseline climate (e.g., 0 °C and 0% precipitation change scenario) corresponds well with the average reported ski season, starting at the end of November and terminating in mid-April. In Vail, however, the reported average season length (mid-November to mid-April) is shorter than the modeled season length. Business decisions to close a ski area due to reduced skier demand and despite sufficient snow depth are common in late season (e.g., April–May). Skier demand is not incorporated in the SkiSim2 operations model and therefore explains the overestimation of season length in this case.

For this sensitivity analysis, a total of 49 climate scenarios were modeled using 2 °C temperature increments (ranging from -4 °C to $+8$ °C) and 10% precipitation increments (ranging from -30% to $+30\%$). For concise presentation, only

Table 1 Climate station and ski area statistics for Vail and Kitzbüehel

		Vail	*Kitzbüehel*
Climate station	Elevation (m)	2509	763
	Lat	39°38′N	47°27′N
	Long	106°22′W	12°24′E
	Mean temperature (°C) Nov–Apr, 1985–2001	−5.5	0.9
	Mean precipitation (mm), Nov–Apr, 1985–2001	264	470
	Mean annual snowfall (cm), 1985–2001	488	411
Ski area elevation (MASL)	Base	2470	778
	Top	3530	1995
	Mean	3000	1387
Average reported season length	From … to (days)	Mid-Nov to Mid-Apr (~152)	End-Nov to Mid-Apr (144 day average between 1982 and 2010)

the results for the mean altitude of each ski area are discussed (3000 MASL at Vail and 1387 MASL at Kitzbüehel. The climate scenarios were produced using the LARS-WG stochastic weather generator (Semenov et al. 1998).

The sensitivity analysis reveals that with the same advance snowmaking in place, Vail and Kitzbüehel differ greatly in their vulnerability to warmer climate scenarios (**Tables 2 and 3**). Applying the '100-days rule' – a coarse indicator of ski area profitability (Abegg et al. 2007) – Vail can be considered snow reliable in all of the climate scenarios (**Table 2**). Reductions in season length are minor in the +2 °C scenarios (up to 10 days), but in the +6 °C and +8 °C scenarios, the ski season could be shortened by up to 1 or 2 months, respectively. Current snowmaking technology is sufficient in Vail to maintain a 100-day season and to guarantee operations during the economically important Christmas–New Year period (Dec 22–Jan 4) up to a warming of +6 °C. Snowmaking requirements increase 59–94% in order to maintain ski season length and operations during this crucial holiday under a +6 °C scenario (**Table 4**). With no change projections for the State of Colorado exceeding +4 °C for the winter months by the 2050s, these results would indicate that the sustainability of skiing in the Vail area are more likely to be challenged by access to water for snowmaking or snowmaking costs than the physical ability to provide a reliable ski tourism product. These results also strongly contradict a highly publicized study by Zimmerman et al. (2006) that proclaimed the 'Ski Industry in Rockies May Be Shut Down by 2050,' even though it did not use any performance indicator relevant to the ski industry or account for snowmaking (**Table 5**).

The situation in Kitzbüehel is very different, as the sensitivity analysis reveals a high vulnerability to moderate temperature increases (**Table 3**). A 100-day season cannot be maintained with current snowmaking technology even under the +2 °C scenarios, though precipitation increases would help offset the negative impact of warming to some extent. In all

other temperature increase scenarios, current snowmaking technology is not sufficient and rapidly declines in volume because temperatures are too warm for efficient snowmaking (Table 5), and the ski season length is close to zero.

These results contrast a broad perception among Austrian ski area managers that snowmaking will provide sufficient adaptive capacity against any potential future climate warming. In a survey of Austrian ski area managers, Wolfsegger et al. (2008) found ski area managers were highly optimistic about their capacity to negate the impacts of a potentially warmer climate. With further adaptation, primarily snowmaking, but including other business and technical options, 68% believed that they could operate their businesses for another 30–45 years and 44% felt their businesses would be viable for at least another 75 years. Because Kitzbüehel is among the lowest major ski areas in Austria, it is more vulnerable than many others, but nonetheless, this analysis suggests ski area managers may be overestimating their adaptive capacity to climate.

The results of this sensitivity analysis for Vail and Kitzbüehel reveal the tremendously different potential for climate adaptation that exists within the ski industry. Kitzbüehel has considerably less potential to maintain ski operations under a warming climate than Vail, despite equal technical adaptive capacity prescribed in the model. Similar differences are also likely to exist between Kitzbüehel and the highest elevation ski areas in the European Alps, as well as between Vail and some lower ski areas coastal climate influence in the States of California and Washington. Further comparative analyses of other ski areas in each ski region, as well as the availability of resources (e.g., water for snowmaking), financial capacity (e.g., for snowmaking investments or infrastructure for non-snow-based tourism products), and social aspects (e.g., tourists response to ski area closures and more variable snow conditions), are needed to estimate the general adaptive capacity of the ski tourism industry in these regional ski markets.

4.24.5 Conclusions and Policy Implications

Based on the available literature on the climate vulnerability of the ski industry, with the possible exception of the Australian and Scottish ski industries, the entire ski tourism market is not at risk to plausible warming trends, but rather the risk is with individual ski operators and the communities that rely on ski tourism, in at risk areas. The probable consequence of warming would be a contraction in the number of ski operators in most regional markets. The impact is likely to be more pronounced at lower elevation ski areas and among smaller ski areas (Scott 2006; Dawson et al. 2009; Steiger 2011a), which have lesser adaptive capacity (see Scott and McBoyle 2007). This has potentially important implications for the development of future skiing demand, as lower elevations, particularly those closest to major urban markets, are often used for beginner ski runs. Whether fewer such ski areas would discourage beginner skiers or possibly diminish the industry's client base over time remains an important uncertainty. There are divergent views on the ski industry and government policies to manage this risk. Some regard a market-based contraction of the sector as healthy, while others contend that for regional economic development and the future of the ski industry, it will be essential to maintain these 'nursery ski areas' through subsidies (by government or the ski tourism industry) (Bürki et al. 2003; Scott et al. 2003, 2008). To some extent this has begun with local governments taking over the ownership of local ski areas and operating them on a non-profit basis like other recreational facilities (such as golf courses or parks) that are supported for the associated community health benefits. This is a policy discussion governments and the ski industry will need to engage in further, as there is tremendous pressure on aging recreation infrastructure in many developed countries and reduced budgets for recreation departments, which cannot prioritize facilities that cater to high cost forms of recreation.

Determining where the ski industry would most likely contract and where it could remain sustainable, if temperatures increase, is fundamental to decision-making and policy decision by the ski industry, investors, real estate developers, insurers, governments, and communities. Assessing the broader socio-economic implications of climate driven evolution of ski tourism markets at the community and regional level (e.g., employment, real estate prices, destination branding, development strategies, and visitation levels) should be a priority for these stakeholders. From a tourism planning perspective, communities that are at risk of losing ski resorts and those where ski resorts are likely to persist will need to adapt to any changes in climatic conditions, though for very different reasons. The former will need to adjust to reduced winter tourism spending, lost employment, and potentially declining real estate prices, and consider strategies for economic diversification and rebranding as a tourism destination (including new tourism product development). The latter will need to plan for increased tourism development pressures associated with the concentration of ski tourism in fewer areas, including water use for snowmaking, real estate development, slope expansion into higher terrain, traffic congestion, and tourist crowding. Adaptation policy will be required to guide the significant economic investment and environmental planning in these alpine communities.

It is essential to emphasis that although a large number of studies have examined the vulnerability of ski tourism to climate, many suffer from key limitations that reduce their validity and therefore limit the relevance for decision makers (e.g., the lack of relevant impact indicators and failure to account for snowmaking as an integral climate adaptation). Consequently, much of the media reporting on the climate impacts on the ski industry has been based on speculation and in some cases misinformation. There are real dangers to this type of misinformation. Flawed reports of impending doom for specific ski areas have been cited by articles in a travel magazine and international real estate investment web site that discussed 'where to buy ski properties to avoid global warming.' Readers are undoubtedly unaware that the statements of this report on some ski areas were scientifically baseless. Through our professional experience in Europe and North America, we have communicated with large investors that have become concerned by media stories on the risks of climate for ski areas. Some European banks imposed financing restrictions on low-lying ski areas based partially on the findings of early studies, which did not account for snowmaking. This misinformation has had a demonstrable impact on the ski industry.

The tourism industry is very image sensitive and is therefore very cautious about even acknowledging concerns about climate risks for fear of adversely affecting their reputation as a destination or as a sustainable business. Nonetheless, it is in the collective interest of ski industry associations, government tourism agencies, destination communities, and financial investors to support sound science on the vulnerability of ski tourism to climate, including the sustainability of key adaptation strategies. Surveys and interviews with tourism operators and industry associations indicate they believe that adaptation to future changes in climate is primarily the responsibility of governments (Scott et al. 2012). Therefore, government will need to provide leadership to facilitate the necessary collaboration among these diverse stakeholders, as well as the policy frameworks to foster sustainable adaptation strategies within the communities that are most vulnerable to large losses in winter tourism and those where ski tourism has the potential to persevere any plausible climatic condition in the coming decades.

Glossary

Adaptation Adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities. Various types of adaptation can be distinguished, including anticipatory and reactive adaptation, private and public adaptation, and autonomous and planned adaptation (IPCC 2001).

Climate change A significant and lasting change in the statistical distribution of weather patterns over periods ranging from decades to millions of years. We focus largely on changes in temperature and precipitation, as they are changing in many regions and have direct impacts on ecosystems and human well-being.

Mitigation Actions that reduce the effects of humans on the climate.

Resilience Amount of change a system can undergo without changing state (IPCC 2001).

Sensitivity It is the degree to which a system is affected, either adversely or beneficially, by climate-related stimuli. The effect may be direct (e.g., a change in crop yield in response to a change in the mean, range, or variability of temperature) or indirect (e.g., damages caused by an increase in the frequency of coastal flooding due to sea-level rise) (IPCC 2001).

Vulnerability The degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes. Vulnerability is a function of the character, magnitude, and rate of climate variation to which a system is exposed, its sensitivity, and its adaptive capacity (IPCC 2001).

4.25.1 Introduction

Virtually all regions of the earth are experiencing rapid changes in temperature, precipitation, and/or other aspects of climate. Human-caused changes in the earth's climate are greatly altering ecological systems, with consequences for human well-being. For example, recent studies have documented shifts in the distribution of plants and animals, advances in the timing of key ecological processes, and extinctions of wildlife populations and species that are likely linked to recent increases in temperature (Parmesan 2006). Such changes are creating regional combinations of environmental conditions that, within the next 50–100 years, may have no current-day analog. The resulting changes in ecosystem function will undoubtedly affect the provision of ecosystem services for human communities.

Maintaining or increasing ecosystem services into the future will require integrating adaptation strategies (actions that help human and natural systems accommodate changes) and mitigation strategies (actions that reduce anthropogenic influences on climate) (Figure 1). Mitigation strategies are those that reduce the magnitude of climate change that will occur. The vast majority of these strategies involve either reducing greenhouse gas (GHG) emissions or sequestering carbon, although they can address any human climate forcing. By contrast, adaptation can be defined as

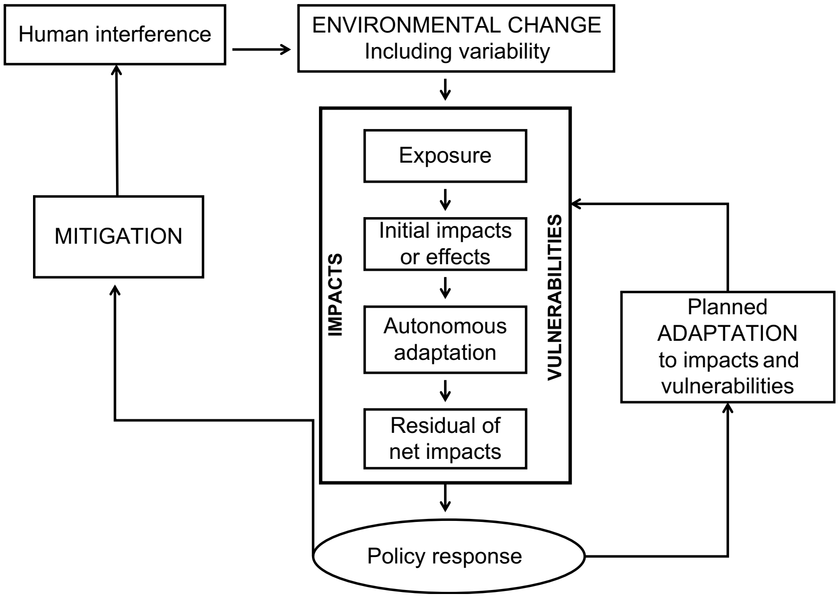

Figure 1 Conceptual diagram of vulnerability, mitigation, and adaptation options associated with climate change. Source: IPCC, 2001: *Climate Change 2001: Impacts, Adaptation, and Vulnerability.* Contribution of Working Group II to the Third Assessment Report of the Intergovernmental Panel on Climate Change. Cambridge University Press.

Table 1 Examples of mitigation strategies aimed at reducing GHG emissions or, in the case of the last category, sequestering carbon to reduce CO_2 concentrations in the atmosphere

Sector	*Mitigation strategies*	*Barriers to implementation*
Transportation	Walkable and bikable communities Increased vehicle efficiency	Lack of safe bike paths Political lobbying of car industry Lack of public transportation Poorly designed communities (sprawl) Cultural values
Shelter	Alternative building materials Passive solar heating Daylighting	Lack of incentives Restrictive building codes Cost of alternative materials
Food	Changes in diet Increased soil organic matter	Cultural values Mass media Demand for low-price food
Energy	Renewable sources Reduced consumption	Cost of new technologies Political lobbying of the energy industry
Carbon sequestration	Reforestation Reduced deforestation	Subsidized clear cutting

alterations to human or natural systems that are designed to reduce the negative impacts of – or exploit the opportunities created by – climate change (IPCC 2007a). Adaptation strategies are much more varied than mitigation strategies, as they are more often specific to particular systems or locations.

Mitigation and adaptation strategies designed to address changes in climate may have additional positive or negative effects on ecosystem functioning, ecosystem services, and human well-being. For example, replacing fossil fuels with renewable energy sources reduces GHG emissions while simultaneously reducing air pollution, acid rain, and smog, as well as asthma and respiratory ailments of humans. Conversely, coastal armoring, the building of seawalls, breakwaters, and jetties, may reduce damage to built structures from the combined effects of sea-level rise and storm surges but such actions can negatively affect coastal ecosystems.

In this chapter, we provide an overview of what will likely be some of the most effective and most important mitigation and adaptation strategies for addressing changes to the climate system stemming from increased GHG emissions. We attempt to cover the entire spectrum of life, from plants and animals to humans, as well as the geophysical properties of our planet that support these organisms. In relation to human populations, we focus primarily on human health as an index of well-being. We also introduce concepts of climate justice. Many of our examples are taken from the United States, although we also include other regions of the world in our analysis as appropriate. We discuss various ways in which mitigation and adaptation strategies can help reduce the magnitude and the impacts of the changes we are likely to experience, as well as improve human health and directly or indirectly affect ecosystem functions and services. Finally, although our analysis sets priorities and orders of importance for an ideal world unimpeded by political considerations, cultural differences, or economic limitations, we include a discussion of the social considerations that we believe must be incorporated into the development and application of mitigation or adaptation strategies.

4.25.2 Mitigation

In the following sections, we briefly discuss what will likely be some of the most effective mitigation strategies for addressing climate change, largely focusing on strategies to reduce CO_2 and other GHG emissions (Table 1). We have grouped these strategies into five categories: transportation, shelter, food, energy, and carbon storage and bioengineering. Although we focus on mitigation strategies that will reduce the magnitude of future climatic changes, we also discuss how these strategies can improve ecosystem functioning and, in some cases, human health.

4.25.2.1 Transportation

Transportation, the movement of people and goods, significantly impacts climate through the emission of GHGs. In 2004, transportation accounted for 23% of the world's energy-related GHG emissions and road transportation represented 74% of the total carbon dioxide (CO_2) emissions from transportation (IPCC 2007b). In addition to being a major source of emissions, transportation also significantly affects ecosystem functions and services. Pollution from vehicles affects ecosystem services such as clean air and water directly, and indirectly through impacts on the plants and animals that regulate ecosystem function. As species are lost from or move into ecosystems the functioning of those systems can change, resulting in altered ecosystem services. Human health is likewise affected by pollution from vehicles (e.g., through chronic lung disease). Transportation networks and moving vehicles also fragment landscapes, reducing the flows of energy and biota resulting in isolated populations and potentially making these populations vulnerable to extirpation and impairing ecosystem functions.

Mitigation strategies that address transportation can be placed into three basic categories: those that increase the efficiency of particular transportation approaches, those that result in a shift in the mode of transportation, and those that reduce the amount of transportation that is needed. Here, we briefly summarize some of the most important mitigation strategies for each category.

4.25.2.1.1 Vehicle Efficiency

A large reduction in GHG emissions can be accomplished by increasing the fuel efficiency of vehicles. For example, increasing the efficiency of light-duty vehicles (cars and small trucks) has the potential to reduce their carbon emissions by up to 50% by 2030 (IPCC 2007b). Such efficiencies can be attained by a combination of reducing vehicle weights, increasing aerodynamics, increasing engine efficiency (particularly diesel engine efficiency), and increasing the use of biofuels and electric and hybrid vehicles. In 2006, the International Energy Association projected that the proportion of transportation energy supplied by biofuels could be increased to 10% (IEA 2006a). Although there is good evidence of successful biofuel markets and programs (e.g., ethanol from sugarcane in Brazil, Goldemberg 2007), there are also negative consequences of increased biofuel production for biodiversity and carbon storage (Fargione et al. 2008; Fletcher et al. 2010). One opportunity for transportation mitigation strategy is the promotion of behavioral changes of drivers. Efficiency of road vehicles could be improved by 5–20% by changes in driving styles, improved maintenance, more efficient tires, reduced idling, and traffic design and maintenance (IPCC 2007b).

4.25.2.1.2 Modes of Transport

A second approach to reducing emissions and many of the other effects of transportation involves changing the ways in which people and goods are moved. One such approach is to increase the use of public and human-powered transportation. Increasing the amount of walking, biking, and use of public transit will depend largely on the available infrastructure and the capacity to provide it. Supporting the development of 'walkable' cities and neighborhoods, bike-friendly roadways and bike paths, carpooling and car-sharing programs, and efficient and safe mass transit are all approaches for shifting the mode of urban transport.

Present transportation alternatives vary by country, with Europe, Japan, and many developing countries having the highest levels of public transportation use, and the United States having the greatest use of personal automobiles. In some developing countries, such as Vietnam or China, personal automobile use is a recent phenomenon, and personal motorized transport is a high aspiration because it conveys increased social status. This disparity in the historical development of the transportation sector will mean that mitigation strategies, barriers, and solutions will have to be location specific and may be dynamic over time.

In addition to the reduction in emissions and the other environmental benefits of shifts to more human-powered transportation, such changes also have clear human health benefits resulting from increased exercise, weight management, and decreases in air pollution (Nemet et al. 2010). Simultaneously improving the quality of public transport and leapfrogging transport-intensive stages of economic growth is needed in many countries to increase higher levels of mass transit use and human-powered transportation (Wright and Fulton 2005). Further reductions in emissions can be made by changing modes of transport for other transportation such as moving more freight by train and ship and less by truck.

4.25.2.1.3 Transportation Demand

The third way to reduce transportation-related GHG emissions is to reduce the amount of transportation that is needed. Decreasing the demand for transportation largely involves changes in human behavior, urban and landscape planning, and changes in technology. Sprawling, low-density urban neighborhoods, such as those found in the United States, perpetuate automobile dependency and transform ecologically functional landscapes into subdivisions. Compact, high-density communities with local urban centers allow residents to work and live in close proximity, and help build social capital among residents and protect natural areas. In conjunction with human-centered transportation infrastructure such as sidewalks, bike lanes, and public transportation, compact neighborhoods reduce car dependency while simultaneously improving the physical fitness of residents. Public green space and urban forests sequester carbon while improving air quality and mental well-being. Increased vegetation, shade trees, and less asphalt combat urban heat-island effects and reduce energy demand for cooling buildings.

Advances in communication technologies also have the potential to reduce the need for transportation. The Internet, online meeting, document sharing, and conference tools have led to an increase in telecommuting and web-based meetings. Similarly, online meetings have begun to replace some in-person meetings and have the potential to dramatically reduce air travel, which can account for a significant portion of an individual's carbon footprint (Fox et al. 2009).

4.25.2.1.4 Barriers and Opportunities

The most significant barriers to implementing mitigation strategies in the transportation sector are long-established personal transportation behaviors and the lack of government interest or capacity to invest in new technologies. Changing the way and the amount that people move around will be very difficult. In the United States and elsewhere, people's relationships with the automobile involve issues of convenience, independence, safety, and social status. Changing these relationships will involve making forms of public transportation more convenient, more effective, and more appealing. Rising fuel costs and commute times may provide some opportunity for implementing transportation-based mitigation strategies. Failing automobile industries and economic crises may provide another. Similar to the projects undertaken by the Civilian Conservation Corps in the United States in the depression of the 1930s, modern-day work relief programs could be used to transform transportation systems. Short of such crises, major changes in transportation will take a combination of regulatory action, education, and incentive programs.

4.25.2.2 Shelter

Housing is one of the most idiosyncratic and regionally variable aspects of human culture. The design of structures is dependent on local climate, land access, available materials, and regional architectural histories. Much of the recent human-caused change in climate stems, in large part, from the way we design, construct, and inhabit the built environment. The following section focuses on a representative selection of design strategies that mitigate the built environment's contribution to carbon emissions and, in many cases, provide cobenefits to human health and local/regional ecological resilience.

4.25.2.2.1 Carbon-Conscious Materials

Building material extraction can have profound impacts on ecosystems and ecosystem services. Mining degrades natural landscapes, destroys habitat, pollutes freshwater environments, and can expose human populations to toxins. Poorly managed lumber extraction leads to deforestation, eliminates suitable habitats, erodes soils, and diminishes the earth's carbon sequestration capacity. Mines that observe best management practices such as land reclamation have fewer negative impacts on climate, local ecosystems, and human health. Sustainably harvested lumber can act as a long-term carbon sink and contribute to the productive and ecological resilience of forests. Rapidly renewable lumber alternatives such as bamboo can offset the demand for slow-growing trees species, rebuild soils, and set the stage for reforestation. However, as with any renewable resource, expanding the production of bamboo in monocultures has the potential to eliminate and/or degrade existing ecosystems.

Eight percent of annual carbon emissions worldwide can be attributed to building material extraction, production, transportation, and installation (Mazria and Kerschner 2008). Choosing building materials with low embodied energy (the cumulative energy of extraction, production, transport, installation, and disposal) and/or that use alternative energy sources reduces the building sector's carbon footprint. Locally sourced materials produce fewer carbon emissions than those transported long distances and both durable materials and those with recycled content help reduce demand for virgin materials. Fully recyclable materials can be reprocessed and repurposed with low energy inputs indefinitely. Removing toxic compounds from material production processes and building products facilitates the recycling or biodegradation of building components. It also helps prevent air and waterborne industrial pollution and associated human illness.

In some cases, it may be possible to choose building materials that actually sequester more carbon than is emitted in their production. The production of Portland cement, the most commonly used cement in construction, is a relatively large source of CO_2 emissions. Magnesium oxide-based cement is as strong as normal Portland cement, but can be manufactured at low temperatures using renewable energy sources. Magnesium oxide is an abundant mineral and is easily recyclable (Smith 2005). As it cures, it absorbs more CO_2 than is released during its production, resulting in a net negative carbon budget.

4.25.2.2.2 Regenerative Buildings

The average lifespan of buildings in the United States is less than 50 years (O'Connor 2004). Design for adaptation – design that easily accommodates changes in configuration and use – extends the life of buildings and stems demand for new construction and virgin materials. When buildings are ultimately decommissioned, design for disassembly facilitates the breakdown and reuse of their constituent components. Both design for adaptation and design for disassembly act upstream from recycling as part of a multicyclic system that repositions well-weathered buildings and building materials as resources rather than wastes, reducing carbon emissions in the process.

Building operations such as heating, cooling, and lighting account for 42% of electricity consumption in the United States (Mazria and Kerschner 2008). Passive design strategies can drastically reduce a building's dependence on carbon-intensive energy production. In cold climates, airtight, well-insulated building envelopes can work in tandem with building orientation, thermal mass, and passive solar radiation to provide thermal comfort and reduce heating bills. In hot climates, external shading, light colored/reflective roofs and walls, and passive ventilation strategies can reduce cooling loads. Daylighting strategies such as light shelves and shallow floor plans bring natural light into interior spaces, reducing the demand for electrical lighting while, at the same time, contributing to the well-being and productivity of building occupants.

Similar to the use of building materials to sequester more carbon than they produce, buildings can generate more energy than they consume. Buildings equipped with photovoltaics, wind turbines, and fuel cells are some of the energy producing technologies that make this possible. Recent advances in computer-aided design software help designers address building performance issues early in the design process and optimize building design for energy use and production. Improvements in digital monitoring and analysis allow occupants to scrutinize building performance and optimize energy use once buildings are operational. In the future, smart buildings and systems will likely respond dynamically to human occupation, weather, daily cycles, and seasonal change, further reducing their energy footprint.

4.25.2.2.3 Compact Communities/Integrated Landscapes

Compact communities (discussed in the transportation section, above), land-use planning, and high-density zoning have the potential to reduce CO_2 emissions, reduce sensible and latent heat fluxes, and improve human health and ecosystem function. Centralized infrastructure and zoning laws that segregate industrial, commercial, agricultural, and residential land use can be beneficial to public health within localities. However, these practices also create a cognitive disconnect between human action and its environmental consequences. They facilitate the transfer of local environmental burdens to regional and global scales, contribute to climate change, and undermine the health of vulnerable populations. Integrated land use and responsibly managed distributed ecological infrastructure have the potential to safeguard public health without the transference of environmental burdens. Synthesizing commercial, industrial, agricultural, and residential precincts, reimagining landscape as infrastructure, and bringing utilities into the public realm raises awareness about the causal relationships that link human activities, environmental degradation, and human health. Urban agriculture, for example, reduces dependence on carbon-intensive industrial food production, minimizes the carbon footprint of food transport, teaches urbanites how to grow their own food, and provides nutrition to communities.

Carbon-conscious materials, regenerative buildings, compact communities, and integrated landscapes have the potential to mitigate the worst effects of climate change. Their success will depend on the ability to implement them not only in developed countries but also in the burgeoning cites of the Global South. We must adapt these strategies to diverse climates, contexts, and cultures and pursue them in tandem with issues of economic development and social equity.

4.25.2.2.4 Barriers and Opportunities for Housing Mitigation Strategies

In modern history, land distribution and regulation have always been the prerogative of governments. For this reason, national, regional, and local governments have a large role to play in housing mitigation strategies. Governments control land-use planning, zoning, and building-code regulations. The ability to act on the mitigation strategies identified above, therefore, is largely dependent upon the regulatory and enforcement environment in a region. In a democratic society, these will in turn be dependent upon the inclination and ability of the state to assume progressive and proactive attitudes toward mitigation.

4.25.2.3 Food

Agriculture releases considerable amounts of GHGs into the atmosphere. In 2005, it accounted for 10–12% of the total global anthropogenic GHGs including approximately 60% of nitrous oxide (N_2O) and 50% of methane (CH_4) of the anthropogenic totals (Rosenzweig and Tubiello 2007; Smith et al. 2008; Burney et al. 2010). Land-use change, nitrogenous fertilizer applications, livestock production, rice farming, and biomass burning are among the major direct sources of GHG emissions. Indirect sources of GHGs from agriculture include the production and/or applications of fertilizers and pesticides, the operation of farm machinery, and the transportation of agricultural products (Burney et al. 2010).

There are multiple opportunities for mitigating climate change impacts through modifications in agricultural practices and food consumption. With respect to agricultural production, mitigation strategies include soil carbon sequestration and the reduction of GHG emissions through altered production methods. With respect to food consumption, society can mitigate the impacts of climate change through changes in diet and by reducing the amount of transportation needed to deliver food (e.g., increasing local food production). Below, we discuss several of these mitigation strategies. The topic of increasing local food production is covered in previous sections on transportation and shelter.

Unlike housing, food is a sector that is potentially much more amenable to individual decision-making and personal choice. This will depend on the relative proportion of food in a household budget. While Americans spend only 5% of their incomes on average on food, the figure for Indonesia is 30%. This indicates that people from wealthy countries would have greater flexibility to support alternative and nonindustrial agriculture through consumer preferences than those from countries where food is a larger part of household budgets.

4.25.2.3.1 Soil Carbon Sequestration by Soil Organic Carbon Management

Agricultural and degraded soils can act as large carbon sinks with the potential to sequester 55–78 Gt of carbon globally (Lal 2004). Soil organic carbon (SOC) is the major component (62%) of this large soil carbon pool (Lal 2004). SOC accumulation is facilitated by adding biomass to the soil and minimizing soil disturbances. The increased SOC improves the physical, chemical, and biological properties of the soil and in turn enhances crop productivity, water holding capacity, and land sustainability under a low-input cropping system. Several agricultural practices facilitate accumulation and retention of SOC in cropland soils, e.g., conservation tillage, mulches, cover crops, manuring, crop rotations, and agroforestry (Lal 2004).

The benefits of these agricultural practices go beyond carbon sequestration. They have the potential to reduce erosion, limit positive feedbacks in drought cycles, and benefit human health. Over the past 40 years, 30% of the world arable land has been taken out of production as a result of erosion (Pimentel 2006). Conventional agricultural practices involving frequent tillage result in soil erosion, which in turn increases concentrations of airborne particulates. These particles can carry pathogens causing infectious diseases and can provide positive feedbacks to drought conditions. Recent climate modeling has demonstrated a positive feedback in the 'dust bowl' drought of the 1930s in the United States (Schubert et al. 2004; Cook et al. 2009). Cook et al. (2009) discovered that a reduction in vegetation cover and the addition of eroded soil dusts to the air resulted in a high temperature anomaly over the northern United States and intensified the drought. As a result of the dust bowl, more than 50% of the surveyed farms comprising 8.7 million acres were seriously eroded, and the economic loss was valued close to US$200 million (AAAS 1936). A combination of warming, drought, and conventional agricultural practices together have the potential to re-create the dust bowl of the 1930s in the Great Plains of the United States (Rosenzweig and Hillel 1993).

4.25.2.3.2 Reduction of GHG Emissions Associated with Livestock Production Systems

The livestock industry is a main contributor to three major climate-related problems associated with global food systems: GHG emissions, reactive nitrogen mobilization, and plant biomass appropriation (Pelletier and Tyedmers 2010). Increases in livestock production and meat consumption are also blamed for the evolution of new and virulent emergent diseases. Any improvement in the environmental sustainability of livestock production will concurrently have a benefit for human health.

Pelletier and Tyedmers (2010) estimated that globally the livestock sector contributed 14% of anthropogenic GHG emissions, 63% of reactive nitrogen mobilization, and consumed 58% of human-appropriated biomass as of 2000. Reduction in GHG emissions in agriculture can be achieved by developing strategies involving improved production efficiency, land-use changes, cropland and rangeland management, and livestock and manure management (Rosenzweig and Tubiello 2007; Smith et al. 2008; Burney et al. 2010; Pelletier and Tyedmers 2010). For example, enhancing production efficiency through agricultural intensification has been credited with the avoidance of 161 Gt of carbon emission globally since 1961 (Burney et al. 2010). This figure highlights that the investment in agricultural research to improve the environmental sustainability of global food production systems (i.e., livestock, crop, and aquatic systems) should be a prioritized mitigation strategy (Lobell et al. 2008; Burney et al. 2010;

Steinfeld and Gerber 2010). Another mitigation strategy to reduce emissions involves shifting livestock production regimes from ruminants to more efficient and lower impact monogastric species (e.g., poultry), well-managed fisheries and aquaculture, and promoting plant-based protein sources (Pelletier and Tyedmers 2010; Steinfeld and Gerber 2010).

4.25.2.3.3 Diet

Changing livestock production from ruminants to monogastric animals and reducing livestock production overall both require significant changes in diet in many parts of the world. This is, of course, where tradition and culture play an important role, yet it is not impossible to induce dietary changes.

Initiatives that reduce the consumption of meat could have dramatic effects on GHG emissions particularly in developed countries (McMichael et al. 2007). Such policies would also reduce impacts on ecosystems and promote other ecosystem services such as a reduction in the clearing of Amazonian rain forests, reduced nitrogen deposition, and a reduction in the application of high-phosphate fertilizers used to grow feed. Reduced meat consumption could also improve human health in developed countries particularly when coupled with incentive structures and educational measures to replace high-fat, sugar-rich foods with more complex diets based on plant proteins. Reduced red meat consumption will likely lower the risk of obesity, diabetes, and several types of cancer (and specifically colorectal cancer), and may reduce the risk of ischemic heart disease (McMichael et al. 2007).

A shift from meat-based proteins to plant-based proteins has the potential to substantially increase the total food calories available for consumption worldwide. Worldwide educational efforts, altered trade policies, shifts in farm subsidies, public health campaigns and new environmental stewardship programs will be needed to achieve a fundamental change in the consumption of meat to achieve large-scale cobenefits for the environment and human health.

4.25.2.4 Energy

Energy consumption and production affect carbon emissions, which in turn affect human health and ecosystem functioning and services. These effects can be divided into the influence of energy consumption and production. While human well-being is in many ways positively affected by the increased availability of energy, there are also negative health effects resulting from the energy consumption and production. Below, we describe potential mitigation strategies for the energy sector.

4.25.2.4.1 Energy Consumption

The US Energy Information Administration reports on energy consumption in the United States in four sectors: residential, commercial, transportation, and industrial. In 2009, consumption across the four sectors accounted for 22, 19, 29, and 30% of overall energy consumption, respectively (US Energy Information Administration 2010). Overall energy consumption, as well as CO_2 emissions from energy consumption, continues to rise. Total US CO_2 emissions from energy consumption were 1390 million metric tons of carbon in 1990 and 1586 million metric tons in 2008 (Research and Innovation Technology Administration 2011).

Reducing GHG emissions through declining energy consumption can be accomplished through a combination of technological advances and changes in human behavior (including the adoption of new or alternative technologies). Several mitigation strategies for addressing energy consumption have been provided in the previous sections on transportation and shelter. In addition to those strategies, increasing the efficiency of appliances and lighting is likely to provide significant reductions in GHG emissions. The most efficient appliances in use today use half to one-fifth of their most inefficient counterparts currently in use (IPCC 2007b). In developed countries, substituting smaller and more efficient refrigerators, washing machines, and other appliances for less efficient ones can substantially reduce energy use. In addition, in developed countries, improvements in the efficiency of electronic devices with inefficient standby modes and power supplies (or more simply unplugging these devices when not in use) can significantly reduce energy consumption. In developing countries where biomass (e.g., wood, dung, and charcoal) is used for cooking fuel, substantial reductions in GHG emissions and improvements in human health may be attained by increasing the efficiency of biomass stoves, fostering a shift to cleaner burning liquid and gaseous fuels, and improving access to electricity (IPCC 2007b).

Significant reductions in emissions can also be made through the use of more efficient lighting. The emissions from electric lighting worldwide are equivalent to roughly 70% of those generated by light passenger vehicles (IEA 2006b). Substituting more efficient lighting technology (e.g., compact fluorescent bulbs and occupancy detectors) can reduce residential energy use by a factor of four or five (IPCC 2007b). Programs designed to increase the energy efficiency of appliances, vehicles, and lighting (e.g., the Energy Star and vehicle fuel economy (CAFÉ)) also have the potential to reduce GHG emissions. Although such programs have not decreased energy use in the United States, they may be partially responsible for halting the growth of per capita energy consumption (US Energy Information Administration 2009).

4.25.2.4.2 Energy Production

Methods for reducing the impacts of energy production on atmospheric CO_2 concentrations, human health, and the environment focus primarily on improvements in an increased generation of renewable energy. Renewable energy sources include those based on waves and tides, biofuels, solar, wind, and hydropower. A shift to renewable energy sources has great potential to reduce GHG emissions, reduce impacts on ecosystems and ecosystem services, and improve human health. Nonetheless, the production of renewable energy will have adverse effects on some ecosystems. Below, we discuss some of the benefits and potential side effects of some sources of renewable energy.

In regions of large tides and tidal currents, such as the United Kingdom, tidal energy could supply as much as 10% of the country's energy supply (Blunden and Bahaj 2007). Two types of systems are in use or are proposed, the tidal barrage and tidal turbines. Tidal barrages allow water to flow into a bay or estuary during flood tide, then they release the water back during ebb tide. As water is released it flows through turbines generating energy. The impact of barrages on fish may be substantial (Aprahamian et al. 2010). Power can also be extracted in the marine environment by turbines in regions of high wave and current energy. However, the ecological impact of the extraction of energy in highly energetic environments is not clear (Shields et al. 2011). The effects of such installations include alteration of benthic (ocean bottom) environments through changes in sediment transport and detrimental impacts on intertidal species through altered currents and nutrient flows.

Biofuels (discussed briefly in Section 4.25.2.1 Transportation) include corn- and sugarcane-based ethanol, wood-based methanol, biodiesel from soy, rapeseed oil, and switchgrass. Biomass is also used in cofiring (combining with coal or other fossil fuels in the burning process) or burned alone as a fuel. Crops can be grown explicitly for biofuels, or residues from farming or forestry can be used as biofuels. Biofuels can also be converted into gasses and then used to fuel gas engines. Nonetheless, many biofuels require significant amounts of land and water to grow them, which brings fuel production into conflict with food production as well as potentially result in a climate effect from the alteration in the surface fluxes of heat and moisture into the atmosphere. In addition, fuel plants may not be as effective as others at absorbing GHGs, and more natural lands converted to agriculture for biofuels will result in increased erosion, decreased water quality, and a loss of wildlife habitat and biodiversity.

Solar energy can be used to generate electricity, heat water, and heat buildings and can be a highly effective form of renewable energy in some regions. Although photovoltaic power generation only accounted for 0.004% of world power production as of 2007, expansion is occurring at roughly 30% per year, largely in developing countries (IPCC 2007b). Hot water production is the second single largest use of energy in residences in both the United States and China. Solar water heating is a cost-effective alternative to other fuel sources in many locations. Similarly, passive solar heating of buildings (mentioned in the Section 4.25.2.2 Shelter) is an effective heating measure in many regions. Finally, solar energy can be used to generate power with solar thermal electric plants that focus solar rays to heat a liquid, which is then used to generate electricity. Passive solar space heating and hot water production likely have the lowest environmental costs. Decentralized photovoltaic use on residences and buildings incurs environmental costs in terms of the production process, but likely have few other negative effects. Conversely, photovoltaic fields and solar thermal electric plants can have large footprints, adversely affecting plant and animal habitat.

Like solar power, wind-generated power is more effective in some areas than others. Wind produced 0.5% of global electricity in 2004 but has been growing at a rate of approximately 28% per year since 2000 (IPCC 2007b). There are potential adverse effects on birds, through collision, displacement due to disturbance, barrier effects, and habitat loss, with more research needed in all areas (Drewitt and Langston 2006; Fox et al. 2006). In addition, the impact of wind turbines on views is perceived to be a substantial barrier to implementation in some communities (Wolsink 2007).

As of 2004, hydropower accounted for 16% of global electricity (IPCC 2007b). Together, large hydropower plants and small and micro hydropower systems can supply power to large municipalities and isolated rural communities with relatively few emissions. Hydropower is not carbon neutral, however, and some studies have estimated significant emissions from hydropower reservoirs (IPCC 2007b). In addition, dams and reservoirs fragment river networks, alter natural flows of water and sediments, and change stream temperatures. These effects are discussed in Section 4.25.3.5 Human-Dominated Systems.

There are several other major renewable energy sources including nuclear, hydrogen, and geothermal. As with the renewable sources described above, there are both benefits and costs to using these other renewable energies.

4.25.2.5 Carbon Sequestration and Geoengineering

Most of the mitigation strategies discussed above are focused on reducing GHG emissions. Additional strategies can be used to increase carbon sequestration, removing CO_2 from the atmosphere. Below, we discuss a few strategies that have been proposed for increasing carbon sequestration and storage as well as much riskier geoengineering proposals.

4.25.2.5.1 Forest Protection Reforestation

Deforestation is one of the largest sources of emission accounting for over 8 Gt CO_2 per year in 2000 (Stern 2006). Although there are many other uses of natural resources that result in carbon emissions, here we focus on mitigation strategies that focus on deforestation. Given the slow rate at which trees absorb carbon dioxide, simply planting new trees in place of those removed does not immediately offset the removal of a tree. A more rapid approach to mitigation is to reduce deforestation. Unlike the majority of emissions that emanate from industrialized countries, most emissions from deforestation are generated by developing countries. Deforestation also itself alters the climate system (Pielke et al. 2007).

Reduced Emissions from Deforestation and forest Degradation (REDD+) is a program of the United Nations that seeks to mitigate climate change by providing incentives to conserve forest cover. Given recognized challenges in REDD (Dickson et al. 2009) – including country by country differences in who owns the forest, who should receive the monetary benefits of preserving the forest, and the reliance of various indigenous groups on forests for livelihood and cultural identity – the program was modified to REDD+ in 2010 to minimize negative consequences and respect the rights of indigenous peoples and members of local communities (Kanninen et al. 2010). Assumed cobenefits include the suite of ecosystem services such as watershed protection; reduction of soil erosion; flood control; provision of fuel, timber, and foods; and cultural and spiritual amenities for local communities. Biodiversity is presumably also enhanced by protecting natural systems. It is possible that forest-dependent communities will be able to maintain access to forests through this initiative. Potential co-harms are increased demand for conversion of other ecosystems if forests are protected, replacement of mixed stands with plantations, and benefits accruing to those not responsible for care and maintenance of the forests.

Prevention of deforestation mitigates atmospheric CO_2 concentrations by preventing the release of stored carbon that occurs when forests are harvested and protecting forest stands that absorb carbon, as well as limits changes in surface energy

Table 2 Examples of adaptation strategies that allow ecosystems and human communities to adapt to uncertain future environments

System	*Adaptation strategies*	*Barriers and challenges*
Freshwater	Increasing connectivity Riparian restoration	Slow uptake of private–public partnerships for restoration
Terrestrial	Protected areas Connectivity	Land costs Extent of land development Property rights arguments
Coastal	Coastal restoration and protection Translocation of people and ecosystems	Few demonstration projects Demand for coastal development
Human dominated	New dams Shifts in the distribution of agriculture	Growing demand for food Growing demand for water

and water fluxes. As of 2011, South America and Africa continue to have the largest net loss of forests and large decreases in carbon storage (FAO 2011). Although tropical forests have been the focus of early REDD efforts, recent evidence indicates that a large amount of carbon can be stored in mangrove forests (Donato et al. 2011), peatlands (Dise 2009), and boreal forests (Carlson et al. 2010), making these potential targets for conservation efforts. Urban forests have also been largely neglected as a potential carbon sink. Escobedo et al. (2011) review the services and disservices of urban forests combined with human health and pollution mitigation as well as carbon sequestration. In some locations, urban forests are on par with other techniques for carbon sequestration and reduction.

4.25.2.5.2 Other Forms of Carbon Capture

In addition to capturing carbon in plants, it may be possible to increase carbon storage in the water and in the earth's crust with various methods. These proposed approaches are still on the scientific fringe and considered to be highly unproven and/or potentially quite risky. One such approach is to capture carbon in the oceans through iron fertilization. In regions of the ocean where there are ample nutrients to drive primary production (photosynthesis) but observations show that chlorophyll is relatively low, the lack of iron is thought to limit the productivity. Over the last two decades, several experiments have attempted to determine whether the addition of elemental iron into the water could cause an increase in algal production and ultimately, as photosynthesis fixes carbon into organic molecules that then sink, the sequestration of carbon in deep ocean sediments. However, the results of these experiments are mixed (de Baar et al. 2005), with the export of carbon being difficult to assess and likely quite modest. At the same time, the impacts on local ecosystems and thus ultimately fisheries in potentially highly productive regions of the subpolar oceans are not yet known. Other carbon sequestration approaches have also been proposed including pumping air down into the oceans, injecting carbon into the ground, and incorporating biochar into soils.

4.25.2.5.3 Geoengineering

Given the magnitude of projected changes in climate and the difficulty in implementing meaningful mitigation measures, some scientists have argued for large-scale efforts to reduce the amount of incoming solar radiation. These approaches are collectively referred to as geoengineering. At present, these approaches are unproven, risky, and, at best, will only address some of the impacts of the human influence on climate. One such geoengineering approach would inject sulfate aerosols into the stratosphere. These aerosols would reflect incoming solar rays and reduce warming. Although such an approach might reduce average global temperatures, it would also likely decrease average global precipitation (Bala et al. 2008) as well as alter atmospheric and ocean circulation patterns. For a given change in radiative forcing, solar forcing is more effective at changing the hydrological cycle than forcing from carbon dioxide owing to differences in the surface latent heat (and thus evaporation) response. While the impact of carbon dioxide fertilization could increase net primary production in terrestrial ecosystems (Govindasamy et al. 2002), ecosystems could continue to be vulnerable due to changes in water resources. In addition, solar radiation management would not address the potentially significant problem of ocean acidification to marine ecosystems.

4.25.3 Adaptation

The majority of both natural and human systems will have to adapt to climate change in some form or the other. A broad array of adaptation strategies has been proposed for reducing the impacts of climate change in both more natural systems and human communities (IPCC 2007a; Heller and Zavaleta 2009) (Table 2). Many of these strategies are either general concepts or strategies that apply to most ecosystems and regions. We begin by describing general concepts and strategies. We then describe some of the strategies that have been proposed for four broad types of ecosystems including freshwater, terrestrial, coastal, and human-dominated systems. For the freshwater, terrestrial, and coastal systems, we focus on strategies that would lessen negative impacts of changing climate on ecosystem functioning and ecosystem services. For the human-dominated systems, we discuss the ways that some of the most often discussed strategies for climate adaptation in these systems will impact (either negatively or positively) ecosystem functioning and the provision of ecosystem services in these and in surrounding areas.

4.25.3.1 General Concepts and Strategies

4.25.3.1.1 Spatial and Temporal Scale

Developing adaptation strategies to address future shifts in climate will require expanding the temporal and spatial scales of plans, policies, and management (Kareiva et al. 2008; Lawler et al. 2010). Three-year, 5-year, and even 10-year plans will fail to address many climate impacts. Future planning will need to address both short-term and long-term changes in systems. To address long-term changes, plans and policies will need to look at least 20 years into the future and will be more useful if they look ahead 50 or more years for many ecosystems and ecosystem services. It will often also be necessary to expand the spatial scale at which systems are managed and policies and plans are developed. As species move and ecosystems change, it will be necessary to think well beyond neighborhood, park, refuge, state, or even national boundaries. Planning will need to occur at multiple, integrated scales and will need to involve local, regional, and sometimes national participants (Kareiva et al. 2008).

4.25.3.1.2 Environmental Justice

While expanding the temporal and spatial scale of climate adaptation strategies, it will be necessary to keep in view local histories, politics, and economies. Scale and locality also play a formative role for issues of ‘environmental’ or ‘climate’ justice. Environmental justice describes the tendency for poor communities to be more vulnerable to environmental degradation. Poor communities tend to bear not only the unequal burden of polluting, destructive, and destabilizing industries but also a disproportionate share of the blame for environmental destruction and responsibility for ameliorating environmental change. For example, polluting industries are often located in poor communities due to cheap land values and the inability of poor communities to politically resist their presence, or a desire to develop jobs at any cost. For instance, swidden agriculturalists in Southeast Asia have been blamed for forest fires despite satellite data pinning large fires to government-sponsored oil palm plantations (Harwell 2000) and Southeast Asian fishers living near toxic riparian runoff from mining have been blamed for polluting local waters by cyanide fishing (Lowe 2006).

4.25.3.1.3 Coordination and Cooperation

The broad spatial scales that are required to address the effects of a changing climate necessitate cooperation and coordination among managers, planners, and policy makers from different jurisdictions, agencies, and management units (Kareiva et al. 2008). They require agencies with diverse mandates and cultures to work together in ways that they have not done in the past. As an example, the US Climate Change Science Program is a federal organization that reaches across federal agencies. The broad scale of climate impacts also requires cooperation across sectors of society and different types of organizations including nongovernmental organizations, local and regional governments, citizen groups, and industry. The US Fish and Wildlife Service’s Landscape Conservation Cooperatives are an example of a system designed to bring together diverse groups of scientists, stakeholders, policy makers, and managers to, in part, address climate change. In addition, as emissions from one locale affect the climate in other locales, addressing the global nature of climate change will involve cooperation at an international level (Hannah 2010). Although, as the above examples demonstrate, some regional, national, and international efforts have been put in place to foster collaboration, more such efforts will need to be made to adequately address climate change.

In addition to cooperation among scientific and political leaders, local and regional stakeholders need to work together as a unified force for social and environmental change. Representatives from the Global North need to appreciate perspectives emanating from the Global South and vice versa. Climate adaptation can be brought into many other environmental and social justice agendas among community advocacy groups and should not remain the purview of the community of knowledge leaders with scientific expertise.

4.25.3.1.4 Resistance, Resilience, and Transition

There are three fundamental approaches to managing systems in a changing climate – promoting resistance, resilience, and transition. Resistance-based adaptation strategies focus on maintaining the current state of a system in the face of climate change or climate-driven changes in the environment. Building a seawall to prevent erosion as sea levels rise and storm surges intensify is an example of a resistance-based adaptation strategy. Resilience can be defined as the ability of a species or system to return to its current state following a perturbation (e.g., Holling 1973). Resilient systems will be able to maintain ecosystem functions and processes and avoid a transition to a new state as climates change. Most of the discussion of climate adaptation to date has focused on managing ecosystems for resistance or resilience. Most of the general adaptation strategies discussed below and the more specific strategies discussed for each of the four types of ecosystems are intended to increase resilience.

The magnitude and rate of projected climatic changes over the coming century will likely make both resistance- and resilience-based strategies insufficient or ineffective in the long run. Managing many systems will require promoting change to a new state. Strategies for promoting change in human-dominated systems may include planting new crops, redesigning road networks, and relocating people. Strategies for fostering change in more natural systems include assisted colonization of threatened plants and animals (see below) and shifting management efforts from one species to another. The outcomes of these more aggressive and forward-looking strategies will be more uncertain, and their implementation will be more controversial. Change is especially hard in social contexts where it is uncomfortable, disadvantageous, expensive, or where the old system is remunerative or beneficial to elites, decision makers, or other small influential groups.

4.25.3.1.5 Adaptive Management

Adaptive management is a flexible approach to managing a system in which the management actions are treated as large-scale experiments (Holling 1978; Walters and Hilborn 1978). It is an iterative process in which the system is monitored following the initial management action and new actions (again treated as experiments) are designed and implemented in response to the results of the initial actions. Adaptive management was conceived for managing highly uncertain systems, and thus it has great potential for managing systems in a changing climate (Arvai et al. 2006). Adaptive management approaches designed to address climate change will likely have four basic steps (Kareiva et al. 2008): (1) assessing the potential impacts of climate change on the system in question, (2) designing management actions – in the form of experiments with testable hypotheses or predictions – to address the potential impacts, (3) monitoring the system for climatic changes and system responses, and (4) using the results of the monitoring to evaluate the effectiveness of the management actions and redesign them as necessary before repeating the four steps.

4.25.3.1.6 Increasing Diversity and Reducing Threats

It is generally accepted that more diverse systems are more resilient to environmental change than less diverse systems. Thus, restoring or protecting the biological diversity of a system will likely increase resilience of that system to climate change (Glick et al. 2009). This diversity can be in the form of species diversity, environmental diversity, or genetic diversity (Schindler et al. 2010). A second, general approach to increasing resilience of species and systems involves reducing the impacts of other factors that reduce the overall resilience of the species or system. For individual species, this might mean reducing harvest, restoring or protecting habitat, eliminating diseases, or reducing human interactions. For ecosystems, this may mean reducing pollutants, restoring vegetation, reducing human use, and controlling invasive species.

4.25.3.1.7 Assisted Colonization

As climates change, many species need to move to track suitable climatic conditions and changing habitats. In some cases, it may be possible to facilitate movement by increasing connectivity of freshwater and terrestrial landscapes (see Sections 4.25.3.2 Freshwater Systems and 4.25.3.3 Terrestrial Systems). However, many species with limited dispersal abilities or that face significant barriers to dispersal will be unable to respond to changing climates. Assisted colonization is one strategy that has been proposed for facilitating climate-driven range shifts (Hunter 2007; McLachlan et al. 2007); also referred to as managed relocation and assisted migration – assisted colonization is the translocation of species outside their native range to facilitate movement in response to climate change. The concept is controversial for both ethical and ecological reasons. Some researchers have highlighted the potential for negative, ecological, evolutionary, and economic impacts, as well as ethical concerns (Ricciardi and Simberloff 2009; Sax et al. 2009). Advocates argue that assisted colonization will be essential for cases in which species will have to move to find suitable environments but will be unable to do so, that many of the potential risks are overblown, and that guidance can be developed for the strategic and informed use of assisted colonization. Several decision-making frameworks and prioritization strategies for applying assisted colonization have been proposed (Hoegh-Guldberg et al. 2008; Richardson et al. 2009). Although assisted colonization will likely be a useful strategy in many systems, there will be specific factors and risks that will need to be considered for particular systems (e.g., in freshwater systems, Olden et al. 2011).

4.25.3.2 Freshwater Systems

Virtually all freshwater systems are already impacted by human activities (e.g., Vörösmarty et al. 2010). Under current climate projections, virtually all freshwater ecosystems will face significant impacts by the middle of this century. Most of these impacts will be detrimental from the perspective of existing freshwater ecosystems and the human livelihoods and communities that depend upon them (Poff et al. 2002). Discussions have broadly focused on rising water and air temperatures, increasing and decreasing precipitation, increasing evapotranspiration, and changing regimes of groundwater and surface runoff. There are four basic types of adaptation strategies that have been proposed for addressing these impending impacts. We define these as ecological water management, connectivity, protected areas, and restoration strategies. Below, we briefly describe some of the specific strategies that have been proposed in each of these areas.

4.25.3.2.1 Ecological Water Management

Increased water scarcity associated with decreased precipitation and increased warming in some regions is likely to prompt the modification of dams and reservoirs to improve storage capacity (see Section 4.25.3.5.3 Managed Aquatic Systems). Traditional water management has generally sought to dampen the natural variability of river flows to attain steady and dependable water supplies for domestic and industrial uses, irrigation, navigation, and hydropower, and to moderate extreme water conditions such as floods and droughts (Postel and Richter 2003). However, the extraordinary species richness and productivity characteristic of freshwater ecosystems is strongly dependent upon, and attributable to, the natural variability of their hydrologic conditions. Thus, large changes to natural flow regimes can have large impacts on species, ecosystems, and society (Postel and Carpenter 1997; IUCN 2000; WCD 2000).

The water needs of humans and natural ecosystems are commonly viewed as competing. However, water managers and political leaders increasingly recognize that there are limits to the amount of water that can be withdrawn from freshwater systems before their natural functioning and productivity, native species, and the array of goods and services they provide are severely degraded (Richter et al. 2003). This has led to a growing realization that society derives substantial benefits both from out-of-stream extractions of water as well as by maintaining adequate flows of water within freshwater ecosystems. In recent years, the water needs of river ecosystems are receiving increasing attention in water-supply planning, offering hope that many rivers can be protected before their health and ability to provide important goods and services is seriously compromised by water development.

Restoring or protecting some semblance of the natural river flow conditions necessary to support ecosystem function (called environmental flows) into the future is one of the most important climate change adaptation strategies for flowing waters. Recent regulatory mandates and policy decisions calling for restoring and preserving environmental flows have led to a reexamination of dam operations for better protection of river health (Watts et al. 2011). For example, the South African National Water Act (1998) calls for the creation of a reserve of water in each river basin to meet both basic human needs and protect river ecosystem health. Similarly, other national directives and international agreements such as the Water Framework Directive of the European Union are providing mechanisms for river protection, including the provision of adequate environmental flows (Postel and Richter 2003).

Maintenance of environmental flows (flows that sustain river ecosystems) is likely to be the highest priority adaptation response for freshwater ecosystems in most contexts. This will require policies and implementation mechanisms to protect (and, if necessary, restore) flows now, and to continue to provide environmental flow regimes under changing patterns of runoff associated with climate change.

4.25.3.2.2 Connectivity

As air and water temperatures warm, many freshwater species will be forced to rapidly adapt to their new environments, to migrate to more suitable habitats, or face extinction (Heino et al. 2009). Responses of aquatic organisms to climate change will be constrained because they are limited to dispersal along pathways of connected water. Consequently, the linear nature of river systems makes them highly prone to fragmentation from waterfalls, dams, and water withdrawals. Such fragmentation can not only limit dispersal and the ability of species to track climate change but also disrupt the completion of life cycles for many freshwater organisms. For many streams, especially in arid and semiarid ecosystems, there is concern that more frequent and severe droughts will lead to the building of more dams and water diversions, further fragmenting stream networks (Seager et al. 2007).

Increasing the connectivity of freshwater systems is one key way to help aquatic systems adapt to climate change. Species responses to climate change will be limited by human-engineered structures, including hundreds of thousands of dams, diversions, and impassable road culverts that exist globally (Nilsson and Schopfhauser 1995). In the United States alone, there are over 80 000 large dams and an estimated 2.5 million or more small impoundments that disrupt the dispersal of aquatic organisms. In recent decades, however, new water laws and programs have helped to increase habitat connectivity by removing or modifying human barriers to movement in river systems. Increasingly, small dams and diversions are being removed for a number of ecological, social, and economic reasons, including the enhancement of longitudinal connectivity for fish migration (Stanley and Doyle 2003). Similarly, temporary barriers such as impassable culverts under roadways are being modified to allow for easier recolonization and movement of fishes (Roni et al. 2008). Although this management strategy may promote the adaptive capacity of species to respond to climate change, the removal of such obstructions can simultaneously increase the risk of invasion by nonnative species and associated diseases, which are major threats to ecosystem structure and function. In fact, the conversion of culverts into permanent barriers has been a common management approach to protect isolated native populations from invasive species spreading upstream (Fausch et al. 2009). Given the complexities of promoting the movement of native species while concurrently limiting the spread of invasive species, it is unlikely that the removal of barriers to enhance habitat connectivity will be a successful adaptation strategy in all areas for reducing the impacts of climate change on ecosystem function.

4.25.3.2.3 Freshwater Protected Areas

In addition to restoring or protecting environmental flows and increasing connectivity within stream networks, it may be necessary to protect the species themselves to allow them to move through or persist in more intensely managed landscapes. In aquatic ecosystems, this may involve increasing the size of existing reserves or creating new protected areas that encompass important freshwater resources and allow for native species and assemblages to persist into the future (Abell et al. 2007). Such acquisitions and agreements ideally would capture a large portion of the geographical, ecological, and geophysical range of multiple species, thus increasing opportunities for organisms to adapt and evolve to changing environmental conditions. Protected areas have historically been a cornerstone of terrestrial conservation – and are discussed in much more detail in that section, below. Nonetheless, protected areas will likely play a major role in protecting aquatic species as climate change and areas could easily be prioritized to provide protection for both terrestrial and aquatic systems in a changing climate (Abell et al. 2007).

4.25.3.2.4 Restoration of Riparian Vegetation

Projected increases in air temperatures, combined with reduced snowpack, earlier onset of spring peak flows, and lower summer baseflows, will have direct implications for the thermal regimes of streams and rivers (Poff et al. 2002). The ecological implications of stream warming are significant. Water temperature directly influences the metabolic rates, physiology, and life histories of aquatic species and helps determine rates of important ecological processes such as nutrient cycling and productivity. In general, warming will produce a general shift in species distribution poleward with extinctions and extirpations of cold-water species at lower latitudes and range expansion of warm-water (often invasive species) and cool-water species into higher latitudes.

Restoring and protecting riparian vegetation – the trees and shrubs that grow along the banks of rivers and streams – has the potential to reduce stream temperatures in certain places. Recent modeling suggests that riparian habitat restoration can play an important role in offsetting the effects of climate change. Battin et al. (2007) used a series of linked models of climate, land cover, hydrology, and salmon population dynamics to investigate the impacts of altered stream flow and temperature on the effectiveness of proposed habitat restoration efforts designed to recover Chinook salmon populations in the Pacific Northwest of the United States. This study showed that in the absence of habitat restoration, basin-wide spawning populations would decline by an average of 20–40% by 2050. By contrast, they found large increases in juvenile rearing capacity associated with proposed riparian habitat restoration, which limited climate-induced declines to 5% according to one climate model and increased salmon abundance by 19% according to another model. However, the model results showed that not all expected climate impacts could be mitigated entirely. In relatively narrow streams, reforestation was predicted to decrease water temperatures by increasing shading, but in wide, main-stem reaches where most Chinook salmon spawn, riparian vegetation had a minor effect on water temperature. In addition to restoring riparian areas, targeted protection of forested riparian buffers using fencing to stop livestock from entering the stream and trampling/grazing vegetation or conservation easements to eliminate farming activities may also help to reduce stream temperatures.

4.25.3.3 Terrestrial Systems

The many adaptation strategies that have been proposed for addressing climate change in terrestrial systems can be loosely grouped into three categories – those that involve protected lands and conservation planning, those that address connectivity, and those that are more species or site specific in nature.

4.25.3.3.1 Protected Lands and Conservation Planning

Protecting land is arguably one of the most effective ways of conserving biodiversity and terrestrial ecosystem services. It is generally assumed that lands that are selected to protect today's species and ecological systems will protect those species and systems into the future. Climate change brings this assumption into question. As climates change and species distributions shift, species will move into and out of reserves. Changes in species composition, the timing of ecological events, and the rates of ecosystem processes will result in changes in the functioning of ecosystems and the services they provide. Many proposed adaptation strategies address these challenges by augmenting current protected areas with additional reserves, parks, and preserves (Heller and Zavaleta 2009; Lawler 2009). These strategies range from broad calls for more protected lands to more sophisticated recommendations about how to select new lands or design new reserves to better protect biodiversity and ecosystem services as climates change.

A number of strategies have been proposed for determining where to put new protected lands to best address the effects of climate change. Some of the simplest strategies involve placing reserves at the poleward or elevational boundaries of the range limits of specific species (Peters and Darling 1985), at major transitions between vegetation formations (Halpin 1997), or at the core of species environmental distributions (Araújo et al. 2004). Others have proposed placing reserves between existing reserves – in the hopes that those new reserves will act as stepping stones allowing species to better move from reserve to reserve. Yet another recommendation involves placing reserves across strong environmental gradients. Reserves that span many different environments will potentially allow species to shift their distributions without leaving the reserve.

In addition to these simple rules of thumb for placing reserves to address climate change, many more sophisticated approaches to selecting areas for new reserves have been proposed. For example, modeled climate-driven shifts in species distributions can be used to select new reserves that will protect biodiversity today and into the future (Hannah et al. 2007; Vos et al. 2008; Hole et al. 2009). Although this approach may prove useful for some species and systems, care must be taken in the use of the models developed to project species range shifts. There are many uncertainties associated with the models themselves and the climate projections on which they rely. Another proposed approach to building a reserve network that will be resilient to climate change involves protecting environments in lieu of protecting species and systems. This approach has been referred to as 'protecting the ecological stage.' This analogy implies that the species and the ecological systems are players and that the soils and topography of a region form the stage on which they interact and evolve. By protecting a suite of diverse environments, it is assumed that one will protect the areas where new ecological systems can develop as climates change (Anderson and Ferree 2010; Beier and Brost 2010). Similarly, others have suggested that more resilient reserve networks will be those that include a diversity of current climates (Pyke and Fischer 2005). Although climates will change, many of the climate gradients generated by latitudinal and topographic patterns will remain. Thus, a set of reserves that protects a diversity of climates today will likely protect a diversity of climates in the future. At least one recent study has applied the concept of protecting environments (topographies, soils, and climate gradients) to a reserve-selection problem (Schloss et al. 2011). One last approach to building a resilient reserve network in a changing climate involves placing reserves in areas that are likely to serve as climate refugia. Refugia are areas that are projected to experience minimal climatic changes and/or have cooler microclimates (Saxon et al. 2005; Hansen et al. 2010; Shoo et al. 2011).

One potential opportunity for climate change adaptation is to consider people as an essential component of species conservation and climate adaptation. While reserve and park systems have a long history of alienating local people, using violence and other coercive measures to separate people and wildlife, in this case, local livelihoods are also threatened by climate change. This provides an opening for a new approach to conservation and a new discourse on the relationship between local people and wildlife.

4.25.3.3.2 Connectivity

As for freshwater systems, improving the connectivity of the terrestrial landscape will be critical for addressing climate change. In response to historical climatic changes, many species shifted their ranges – moving toward the equator as ice sheets advanced and moving poleward as the ice sheets retreated. Today's species will have a much harder time responding to current and impending climatic changes. Present-day landscapes – unlike the landscapes of the distant past – are fragmented by roads, agricultural fields, and residential development. Given that many species will have trouble moving across these human-dominated landscapes, it will be essential to reconnect fragmented landscapes to allow species to respond to shifting climates. Not surprisingly, improving landscape connectivity was the most often recommended climate change adaptation strategy in a recent review of the literature (Heller and Zavaleta 2009).

Many of the recommendations for increasing connectivity involve designing corridors that connect current protected lands. Traditionally, such corridors have been designed for particular focal species, and they have connected reserves or remaining fragments of habitat. However, corridors that facilitate species ranges shifts and the reshuffling of ecosystems will need to connect what is habitat for a species today with an area that may become habitat in the future. In this way, corridor design will need to evolve to address climate change. One such approach to developing corridors for addressing climate change involves basing the corridors on environmental gradients instead of on the current vegetation (which is often used as a measure of habitat) (Beier and Brost 2010). Another approach uses projected changes in climate to orient corridors (Ackerly et al. 2010). A third method involves using modeled shifts in species distributions to identify potential routes that species would need to take to move from currently suitable climates to places where climates will likely be suitable in the future (Williams et al. 2005; Rose and Burton 2009). These three approaches are based on different assumptions and have different levels of associated uncertainty. In general, the uncertainty increases with the intensity of modeling required to identify the corridor, and thus the first of the three approaches has the least inherent uncertainty and the last of the three has the most.

Although corridors may be useful for some species, they will not be feasible or effective in all places or for all species. In addition to designing corridors to facilitate species movements, it will likely be necessary to improve the permeability of the landscape in general (Franklin and Lindenmayer 2009). Increasing landscape permeability will involve changing the way we use and manage the landscape. Changes in forest harvest practices from clear-cuts to selective, retention harvests can increase the connectivity of forested landscapes. Landscape planning and zoning for residential development can reduce landscape fragmentation. Windbreaks, fencerows, and crop choices can be used to increase the connectivity of agricultural lands. At a finer scale, choices of landscaping plants, road placement, and wildlife over- and underpasses can increase landscape permeability.

4.25.3.3.3 Species- and Ecosystem-Specific Strategies

Protected lands and connectivity increase species ability to adapt to changing climates at relatively large spatial scales. In general, they address species movements. Adaptation strategies are also needed at finer scales. In particular, strategies are needed that address individual species and ecosystems. Many of these finer scale approaches tend to involve reducing temperatures or otherwise offsetting the exposure to the changes in climate or climate-driven changes in environmental conditions. For example, it may be possible to reduce temperatures by restoring vegetation to provide shade (Wilby et al. 1998; Wilby and Perry 2006). It may be possible to reduce the impacts of changing fire regimes through forest management practices. Fire suppression policies, may, for example, have particularly severe ramifications in a climate in which fires will generally be larger and more frequent. It may also be feasible to provide supplemental water for particularly vulnerable plants or animals in times of drought or during heat waves. Similarly, shade shelters could be provided to help some animals weather heat waves in extreme climates. Although some of these strategies may prove useful in the short term, many will be neither cost-effective nor long-term solutions.

Another system-specific approach to addressing climate change involves altering species composition or community structure in a way that allows a system to better cope with climatic changes. For a forested system, this may mean planting new species or planting seeds of the same species that have a different genetic makeup (Millar et al. 2007; Glick et al. 2009). Likewise, for grasslands and shrublands, this may mean choosing different species or strains for restoration purposes. Moreover, it may mean facilitating the transformation of an ecosystem – for example from a shrubland to a woodland or from a shrubland to a grassland. In many cases, the first species to move into these transitioning systems may be invasive species. Facilitating the transition to a new state using species native to the region may, in many cases be preferable to having new systems dominated by invasive species. These extreme cases will require ex situ conservation strategies, including seed banking and captive breeding to ensure the long-term survival of the species.

4.25.3.4 Coastal Systems

The interface between the land, sea, and air found in coastal areas is a high-energy system subject to storms, winds, and tides. It is also where the majority of protein comes from in many regions of the world. Many vital ecosystem services are provided along coastal margins of continents and islands. Fringing coral reefs and mangrove forests buffer wave energy, which reduces erosion along the coast. These systems also provide critical habitat for many species, especially nursery areas for provisional services such as fisheries. In many areas, sea-level rise and associated storm surges will make it difficult to protect these systems and the services they provide. Nonetheless, there are two main approaches that will likely prove most useful in coastal systems: building resilience through protection and restoration and facilitating the transition to new ecosystems.

4.25.3.4.1 Protection and Restoration

One of the more beneficial ways, from both an environmental and economic standpoint, to adapt to predicted changes from climate change is by protecting and restoring natural systems that provide multiple ecosystems services. This would include protection of human infrastructure from sea-level rise and increased inundation. Protection and restoration of natural buffers such as barrier islands, mangroves, and coral reefs not only require little financial construction and maintenance but also maintain the wealth of ecosystem services associated with these systems, which include nursery and rearing habitat for many commercial seafood stocks such as fish and shrimp, recreational and cultural opportunities for humans, and protection from inundation. Some natural protection features such as sea ice cannot be maintained in the face of increasing temperatures. In Alaska, the loss of sea ice and melting of permafrost due to warming ocean and air temperatures has exposed the shore to wave energy that used to be absorbed or damped by sea ice or frozen soils. Undoubtedly, ecosystem services that depended on that sea ice protection have also been lost.

Many regions have seen a huge decrease in the area covered by mangroves as coastal areas are drained and mangroves removed for aquaculture. Worldwide, it is estimated that more than 50% of mangrove forests have been destroyed or converted to other uses. On a local scale, many areas have lost all of their mangroves. This loss destroys a wide range of ecosystem services provided by these forests, which range from carbon sequestration to flood protection, spawning, and rearing grounds for many fish and other marine species. Restoring mangrove forests results in increased storm surge protection for natural and human coastal systems, provides nursery habitat for many commercially important fisheries, and stores sediments that may damage offshore coral reefs.

Worldwide, corals exhibit well-documented environmental adaptability over time scales of weeks to thousands of years.

Corals are actually two creatures that live together in a symbiotic relationship. Zooxanthellae are the algal component of corals that provide nutrients generated from photosynthesis to the animal component. Different zooxanthellae species and different species of corals in general have differential environmental tolerances. For example, some corals near the Arabian Peninsula exist under conditions of salinity and temperature that are greater than near-term predicted future average salinities and temperatures resulting from climate change. These adaptive changes likely operate on a decadal time scale. Thus, in some cases, it may be possible to identify particular species or zooxanthellae and algal combinations that are more resilient to warming. Protecting coral reefs from other stressors such as excess sediment and/or nutrient and pollutant inputs from terrestrial sources and unregulated diving can increase the coral's ability to adapt to increased water temperatures. Technological adaptation measures include using sprinklers to create roughened sea surface to decrease light penetration or covering reefs with shade cloth to limit bleaching of corals.

4.25.3.4.2 Transition and Migration

As sea levels rise, many coastal systems will need to migrate inland. When there are extensive human uses of coastal space or urban buildup, space for ecosystem recovery and migration of species will not be available. Providing space for the migration of biotic elements of the coastal system at the same time as when human populations are forced to move would provide cobenefits for coastal life and human communities. Ecosystems will usually adjust to changing salinities and water levels, and the services provided by the system will be maintained where conditions are suitable. For example, in 1996, a subdivision east of Houston in Baytown, Texas, was bought out, the structures removed, and the entire area restored to coastal wetlands. A more extreme example of planned retreat is the Maldive Islands. Their current plan is to exploit the current coastal amenities, primarily beaches and coral reefs; secure capital with which to train younger citizens; and prepare them for relocation to other countries such as India, Sri Lanka, and Australia. In the short term, there are negative consequences to ecosystem services due to commercial and touristic exploitation, but in the long run, by abandoning the islands, the system will be able to come to a new ecological state.

In some cases, removing human infrastructure will be a necessary but insufficient means of fostering landward shifts in coastal systems. In such cases, it may be necessary to facilitate the shift in natural systems and stabilize soils by planting more coastal species inland as water levels rise. Such actions have been taken as part of the Alligator River climate change adaptation project on the North Carolina coast in the southeastern United States (Pearsall 2005, Pearsall and Poulter 2005).

4.25.3.5 Human-Dominated Systems

Here we describe some of the adaptation strategies that have been proposed for built environments, agricultural systems, and managed freshwater systems. We explicitly focus on how the most commonly proposed strategies could affect associated ecosystems.

4.25.3.5.1 Built Environments

The severity of climate change impacts will depend, in large part, on our ability to transform the built environment in response to changing conditions. The following section discusses some of the climate change adaptation strategies that will likely take place in built environments and the effects that these strategies may have on ecosystem functions and services. We briefly discuss human migrations, flood control, sea-level rise, increased water storage, and urban heat-island effects.

Perhaps the most basic form of climate change adaptation involving the built environment is human migration. Vulnerable populations will be forced to abandon their homes, relocate, and rebuild. They will displace resident populations and open up the possibility of conflict in the process. The bulk of climate change-related human migration that is already occurring involves movement from rural areas to cities in developing countries. Unplanned urban growth will fuel the expansion of informal urban settlements, and by 2050, 3×10^9 people, one-third of the world's population, may inhabit urban slums. In both rural and urban environments, proactive planning and resettlement strategies that identify populations at risk and relocate them stand to drastically reduce long-term human hardship stemming from climate change. They can also protect vital ecosystems from the degradation associated with unplanned development. However, resettlement can have profound negative impacts. Poorly executed, it can degrade indigenous culture, undermine traditional livelihoods, destroy social networks, and deepen poverty by distancing poor communities from employment opportunities. Given these dangers, in some cases, it is preferable to fortify communities against climate change impacts in place. This approach introduces improvements to infrastructure and housing, builds upon the prior efforts of communities, and preserves social networks.

In many regions, climate change will result in increased rainfall and flooding. Conventional approaches to storm water management rely on defensive hard structures. Water runs from impermeable concrete and asphalt surfaces into storm drains, culverts, and concrete embankments. Rivers are straightened, channelized, and isolated from their natural floodplains to accommodate human settlement. As flood events become more intense and frequent with climate change, storm water management strategies must evolve. Rather than take a defensive stance, they should promote the coexistence of humans, habitat, and water. Soft infrastructure or low-impact development strategies, such as permeable paving, green roofs, green walls, rain gardens, bioswales, and constructed wetlands offer a promising alternative to conventional storm water infrastructure. They promote groundwater recharge, reduce flooding, and improve water quality with downstream benefits to aquatic habitats. In areas of severe flood risk, resettling residents on higher ground and reintroducing rivers to their floodplains protects human populations, dissipates flood energy, and creates wetland habitat. Through temporal land-use practices such as intermittent farming, floods become an asset rather than a threat, depositing sediments that enrich agricultural lands.

By 2050, rising sea levels may displace as many as 162 million people (Myers 2002). Like conventional storm water infrastructure, conventional seawall infrastructure relies on defensive hard structures. As sea levels rise, existing levees will become obsolete. Here again, soft-infrastructure strategies offer a promising alternative. Graduated transitions from sea to land including manmade offshore islands, expansive shallows, and coastal marshes act as buffers for storm surge better equipped to absorb the impacts of extreme weather events. They provide habitat for marine species and, in coastal cities, public space for recreation when conditions permit.

In places like coastal Peru and sub-Saharan Africa, disappearing glaciers and reduced precipitation will increase the frequency, duration, and impacts of drought, undermining food and water security. A number of interventions in the built environment can help communities cope with water scarcity. Increasing water storage at scales ranging from dams to urban reservoirs and household rainwater barrels helps bolster water supplies during prolonged dry periods. In coastal areas, desalination plants and, in select localities of South America and Africa, fog harvesting may prove to be viable alternative water sources. Ecological sanitation technologies such as dry toilets and gray water wetlands conserve potable water for drinking and, as part of a network of integrated ecological infrastructure systems, irrigate and provide nutrients for urban farms and forests. They also help prevent contamination of local water bodies, preserving their viability as sources of potable water and ecological integrity. Further impacts of, and opportunities associated with, these various adaptation strategies are discussed in the Sections 4.25.3.5.2 and 4.25.3.5.3.

Cities in developed countries are on average 1–3 °C hotter than the surrounding countryside (UN Human Settlements Programme 2011). Higher urban temperatures increase energy use, degrade urban air quality, raise the temperature of urban storm water runoff, and contribute to general discomfort, respiratory illnesses, heat stroke, and other heat-related illnesses. Warming in conjunction with increased urbanization will amplify urban heat-island effects and their associated impacts.

Several strategies can help reduce urban temperatures. At the scale of the site, urban trees with high, dense canopies, strategically planted around buildings, in parking lots, and along streets permit the passage of air, shade heat-absorbing surfaces, and cool the atmosphere through evapotranspiration. They also reduce the temperature of runoff water. Green roofs perform a similar function on roof surfaces. Buildings and landscapes constructed from materials with high solar reflectance or albedo absorb less heat and reduce urban temperatures. At a larger scale, streets oriented parallel (or up to 30°) to prevailing winds, permeable networks of public open space, strategically situated low-rise buildings, and gaps between high-rise structures increase the air permeability of urban environments.

4.25.3.5.2 Agricultural Systems

Increased temperatures and changes in precipitation regimes are likely to have negative impacts on global food security by worsening the existing regional disparities between developing and developed countries (Easterling et al. 2007; Rosenzweig and Tubiello 2007). This is supported by the prediction that a moderate warming accompanied with elevated CO_2 concentrations is likely to lead to an increase in crop productivity of developed countries in temperate mid and high latitudes, whereas even a slight increase in temperature could damage crops that are already growing at supraoptimal temperatures in countries located in tropical, low latitudes (Easterling et al. 2007; Easterling 2010). As in other systems, even with significant mitigation efforts, adaptation strategies will be necessary to address the impacts of climate change on agriculture.

Adaptation strategies for more resilient agricultural systems may include altering the timing and location of cropping, switching crop species and cultivars, selecting livestock breeds, crop rotations, and efficiently using and managing water resources. These types of adaptation strategies have been referred to as autonomous strategies (Easterling 2010). Implementing some of these strategies, such as changing the type of livestock that is grazed or changing crop rotations could have profound effects on ecosystem functioning. However, in general, these types of adaptation strategies will have environmental impacts smaller than more intensive strategies that are designed to transform systems.

For many agricultural systems, the magnitude of climatic changes will necessitate more intensive planned adaptation strategies that foster significant transformations of systems or infrastructures (Easterling 2010). Such intensive strategies will be particularly important for sub-Saharan Africa and South Asia where climate will have major impacts on agriculture (Lobell et al. 2008; Nelson et al. 2009). These planned adaptation options include developing new infrastructure (e.g., irrigation infrastructure, transport and storage infrastructure, and efficient water use and reuse technologies), investing in new technical and management options (e.g., crop and livestock improvement, enhancing germplasm), shifts in the distribution of agriculture (e.g., abandoning some areas and farming new lands), and building the capacity to make continuing adjustments. Here, we discuss two of these strategies – improving crop performance and water conservation – in more detail.

Stresses on crops due to extreme heat and pest and pathogen pressures are likely to increase with climate change (Deutsch et al. 2008; Battisti and Naylor 2009). Multiple adaptation options are available for improving crop performance in the face of such climate-driven stresses. First, in conjunction with conventional breeding, crop improvement through genetic engineering is seen as an effective adaptation tool in a changing climate – although public opinion is often divided on the use and consequences of genetically engineered crops (MacDiarmid 2007; Jones 2011). A second approach involves maintaining crop genetic diversity by, for example, collecting and storing the diversity of current cultivars or local landraces. A third adaptation strategy involves exploiting symbiotic relationships between crops and other organisms. For example, it has been shown that numerous fungal and bacterial endophytes confer stress tolerance to heat, drought, salinity, and pathogen attacks (Rodriguez et al. 2008; Rodriguez et al. 2009), and others promote growth and fix atmospheric nitrogen (Doty et al. 2009; Xin et al. 2009). Other strategies include the application of kaolin particle films to reduce heat stress and photoinhibition and to mitigate pest damage (Glenn et al. 1999; Glenn 2009) as well as the incorporation of biochar into soils to confer numerous agronomic benefits that enhance crop performance and stress tolerance (Marris 2006).

Irrigated agriculture accounts for about 70% of the world's freshwater withdrawals (Rosegrant et al. 2009). With increasing global population, the demand for irrigated agriculture will continue to increase globally because realized crop yields normally increase considerably with irrigation. Adaptation strategies that foster more efficient use of water in agriculture will be critical for achieving global food security while conserving water in a changing climate. These strategies will include institutional water management reform, economic incentives for efficient water use, and infrastructure investment for efficient irrigation and water delivery systems (Rosegrant et al. 2009). The 'virtual water' trade through crop products from water-abundant to water-deficit areas should be considered as one of the key adaptation options to climate change (Rosegrant et al. 2009; Easterling 2010). Improving crops for higher water-use efficiency (i.e., greater yield with less water use) should be a goal for genetic, ecological, and agronomic options of adaptation discussed above. Alternative strategies of increasing water storage capacity with dams and increasing the number of stream diversions for agriculture will, in contrast, have significant impacts on aquatic ecosystems (see the Section 4.25.3.5.3 Managed Aquatic Systems).

4.25.3.5.3 Managed Aquatic Systems

As discussed above, changes in temperature and precipitation are likely to lead to changes in the demand for water. Projected climatic changes will likely lead to increased demands for residential use, irrigated agriculture, hydropower production, and carbon capture and storage technologies. In some regions, current water management may not adequately cope with the impacts of changing precipitation regimes and increased evaporation on the reliability of water supply, flood risk, health, agriculture, energy generation, and freshwater ecosystems (Palmer 2008). Adaptation strategies designed to address water management for human uses will either directly or indirectly affect ecosystem functioning and ecosystem services. In addition to the adaptation strategies for addressing water demands for agriculture and residential use (addressed to some extent in Sections 4.25.3.5.1 and 4.25.3.5.2), other important adaptation strategies for managed aquatic systems that will impact ecosystem functions and services include increased extraction of groundwater, improving storage capacity by building or modifying dams and reservoirs, desalination of seawater, and expansion of rainwater storage and water transfer (Bates et al. 2008; Hirji and Davis 2009).

Improving storage capacity by building or modifying dams and reservoirs is likely to be one of the most common regional responses to decreased water availability and increased demand for water. The great utility of running water has resulted in the extensive exploitation of streams and rivers by humans throughout the world, a process greatly facilitated by the construction of hundreds of thousands of dams globally (Nilsson et al. 2005). By capturing high river flows and releasing the water in a carefully controlled manner, dam managers can deliver steady and dependable water supplies to downstream areas, protect settlements from floods, or generate power. Although human manipulation of the world's river flows has provided many societal benefits, it has also caused considerable ecological damage and the loss of important ecosystem services valued by society (Baron et al. 2002). Flow regulation for hydropower and storage, diversion for human use, and extraction of groundwater connected to stream systems often significantly affect the natural seasonal and interannual variation in river flow, commonly referred to as the natural flow regime (Poff et al. 1997). A natural flow regime is needed to sustain the complex riverine and riparian ecological functions and processes that support native biodiversity and provide myriad ecological services including maintaining water quality, recharging groundwater, and nutrient cycling (Naiman et al. 2002).

Facing an ominous future of increasingly severe water-supply shortages in many areas of the world, social planners and government leaders are exploring strategies for ensuring that enough water of sufficient quality is available for use by future generations. Human demands for water are expected to increase under a warmer climate, exacerbating current management problems. Increasing demands for irrigation and industrial cooling water could conflict with the increasing demands for municipal water supplies resulting from urban growth. Climate-induced changes to water availability and increasing human demand for water are likely to prompt the construction or modification of dams and reservoirs to improve storage capacity and enhance water security (WCD 2000; Palmer 2008). For instance, by storing water in reservoirs, water managers capture high flows during wet years or seasons to supplement water supplies at drier times, thereby maximizing the reliability of water supplies and certain economic benefits each year. For regions where increases in runoff variability or more prolonged drought conditions are associated with climate change, the pressure to build water-supply reservoirs will be great.

Although the construction of additional dams and reservoirs will undoubtedly provide many societal benefits, a rich body of scientific knowledge has shown that river regulation also causes considerable ecological damage and the loss of important ecosystem services valued by society (Baron et al. 2002; Postel and Richter 2003). River ecosystem health deteriorates when natural flows of water, sediments, and organic materials through a river system are substantially disrupted or modified by human activities (Poff et al. 1997; Richter et al. 2003). River damming and associated environmental alteration is now widely recognized as a leading cause of declines in freshwater biodiversity globally (Bunn and Arthington 2002). Dams have also been implicated in the loss of commercial fisheries in many estuaries and coastal areas, and in the degradation of other natural ecosystem products and services worldwide (WCD 2000). In addition, reservoirs increase the loss of water due to evaporation. Finally, as mentioned above, reservoirs emit substantial quantities of carbon dioxide and methane into the atmosphere (St. Louis et al. 2000), and therefore, the creation of additional reservoirs is likely to further promote climate change.

In many regions, impending water shortages will also lead to greater interest in desalination as a technique for tapping into the vast and infinitely tempting water supplies of the sea. Recent improvements in reverse osmosis technology, coupled with the rising cost and increasing unreliability of traditional water supplies both currently and projected in the future, are making desalination a water-supply option with major plants in operation, in planning, or under consideration in Europe, North Africa, North America, Australia, China, and India. Like most large-scale industrial processes, making water has a number of actual or potential impacts on aquatic goods and services (WWF 2007). Emerging issues include significant cost and pollution emitted by desalination plants and the mostly unknown, but potentially substantially, effects on freshwater and coastal ecosystems. Intake pipes can remove larvae and small marine organisms, and discharge from desalination plants can elevate levels of salt and other constituents of seawater such as boron; dead sea life, which consumes oxygen while decomposing; chemicals added to change the composition of the water for processing, as well as reducing contamination and clogging of filters and membranes; corrosion by-products; and the heat added for or during processing. Finally, water manufacturing is an energy-intensive process.

4.25.4 Social Considerations in Planning for Mitigation and Adaptation to Climate Change

Although increasing GHG concentrations and the resulting increasing temperatures are global phenomena, the globe will often be an inappropriate scale for developing mitigation and adaptation strategies. Human activities generate differential risks and vulnerabilities that vary with location due to differences in social, political, cultural, and economic conditions (Beck 1992). Although, in one sense, all people are vulnerable to catastrophic climate change, at another more fundamental level, the risk of climate change impacts (along with blame and responsibility) are unevenly distributed. We can begin to think of the unequal distribution of the vulnerability to climate change as a scale issue.

Mitigation and adaptation strategies can be applied at multiple, and often overlapping, scales. At the finest scale, the development of mitigation strategies will depend on local leadership and the attitudes of local populations and individuals toward climate change. At national and international levels, mitigation efforts will be organized through large and formal programs and institutions (e.g., UN-REDD). Although some adaptation strategies will be national and international in nature, much adaptation will take place at finer scales of communities and regions. A hallmark of climate change as a global phenomenon is that leadership and coordination across local, national, and international scales is important for ameliorating its effects. In turn, coordination across scales will entail understanding local climate risks and local and regional understandings of the causes of climate change and the costs and benefits of different mitigation and adaptation strategies.

The effectiveness of any mitigation or adaptation strategy (building codes, population planning, dietary changes, etc.) depends on its acceptance in local, regional, and national communities. Social impediments to adoption of climate change strategies include ideological outlooks, structural constraints, and cultural barriers. For example, free-market ideologies can impede the ability of governments to invest in alternative energies; agricultural subsidies and corporate monopolies on agricultural inputs may create structural barriers to alternative agriculture; and cultural norms for relative water and energy use, family size, or the flavor and texture of food can inhibit conservation of resources and changes in diet.

There is a clear disparity between societies that have contributed the most to GHG emissions and those that will likely suffer the direst consequences of climate change. At the international level, efforts to shift blame from the activities of the rich to the actions of the poor have been used to shirk the responsibility to mitigate climate change and to impede the development of global mitigation strategies. The dispute between the Global North and South over who caused climate change and who must now take responsibility for mitigation is by now well known. Countries in the Global South argue that northern countries have already developed their economies relying on fossil fuel consumption and now, when it is their turn to develop, they are asked to put restrictions on their energy consumption and natural resource use. Meanwhile, the United States has used the reluctance of developing countries to cap emissions as an excuse for inaction on its part. Mitigation and adaptation activities that do not take globally inequalities in wealth, resources, and adaptive capacity into account, or insist on 'equality' in action in a demonstrably unequal world cannot be effective.

Addressing population growth clearly plays a key role in both mitigation and adaptation strategies. However, focusing on population size while ignoring global patterns in the consumption of resources and the distribution of wealth will result in failed policies and strategies. The world's human population is approaching 7×10^9, and a growing population inevitably means greater demand for the numerous goods and services supported by terrestrial and aquatic ecosystems. While the availability of resources has seemingly stretched beyond the direst predictions of several decades ago, the crisis of over-consumption – namely, of coal and other fossil fuels that produce GHGs and contribute to climate change – is simultaneously becoming clearer. While trends over the past several decades suggest that population growth is a significant driver of CO_2 emissions (Bongaarts 1992; Dietz and Rosa 1997), it is also true that urbanization, aging, and changes in household size similarly affect energy use and emissions (MacKeller et al. 1995; Cole and Neumayer 2004). Particular point sources of GHG emissions from energy consumption in developed countries, like the internationally managed oil fields of Nigeria or emissions from the recent Iraq war, which since 2003 has released over 140 million metric tons of carbon dioxide, the equivalent of adding 25 million new cars to American roads (Reisch and Kretzmann 2008), should bear at least as much scrutiny as the desires of third world women and men to bear children. An overarching emphasis on population detracts from a nuanced understanding of the multiple drivers of GHG emissions.

It will be ineffective to focus on the effects of climate change on ecosystems without considering the concurrent effects on human well-being and vice versa. Disparities in climate change risk and human health often overlap, and human health and environmental health are intricately intertwined. Although diseases are often approached as singular phenomena, good models exist that demonstrate the interactive effects of multiple morbidity factors on health outcomes and disease trajectories. For example, interactions between acquired immune deficiency syndrome and tuberculosis, or diabetes and severe acute respiratory syndrome, have synergistic impacts on patients that must be understood together. Likewise, social attributes, like poverty or exposure to racism, interact with disease conditions to increase the damaging effects of disease. Such interactions have the potential to influence the effects of climate change on disease movement and clustering, disease interactions, and the impact of climate change on global health (Baer and Singer 2008). Human action and human vulnerability to such interactions between climate, disease, and the environment are structured by social and economic inequality, and thus mitigation and adaptation strategies will need to take these inequalities into account.

What is clear from a social and political perspective on mitigation and adaptation is that no one set of mitigation or adaptation strategies will be applicable to all people in all places. Suggested approaches to either mitigation or adaptation will involve costs and benefits that are unequally distributed across nations, populations, and societies. There will, for example, always be those who can escape pollution with air filters and private vehicles, use air conditioning to survive heat waves, have access to global food markets and multiple water sources, and those who cannot. The most effective mitigation and adaptation strategies, therefore, will address both climate change and environmental justice.

Acknowledgments

EDITOR-IN-CHIEF

Dr Roger A. Pielke is currently a senior research scientist in CIRES and a senior research associate at the University of Colorado-Boulder in the Department of Atmospheric and Oceanic Sciences (ATOC) at the University of Colorado in Boulder (November 2005—Present). He is also an emeritus professor of atmospheric science at Colorado State University and has a 5-year appointment (April 2007—March 2012) on the Graduate Faculty of Purdue University in West Lafayette, Indiana.

He has studied terrain-induced mesoscale systems, including the development of a three-dimensional mesoscale model of the sea breeze, for which he received the NOAA Distinguished Authorship Award for 1974. He has worked for NOAA's Experimental Meteorology Lab (1971—74), The University of Virginia (1974—81), and Colorado State University (1981—2006). He served as Colorado State Climatologist from 1999—2006. He was an adjunct faculty member in the Department of Civil and Environmental Engineering at Duke University in Durham, North Carolina (July 2003—06). He was a visiting professor in the Department of Atmospheric Sciences at the University of Arizona from October to December 2004.

He has served as chairman and member of the AMS Committee on Weather Forecasting and Analysis, and was the chief editor for the Monthly Weather Review for 5 years from 1981 to 1985. In 1977, he received the AMS Leroy Meisinger Award for ‘fundamental contributions to mesoscale meteorology through numerical modeling of the sea breeze and interaction among the mountains, oceans, boundary layer, and the free atmosphere’. He received the 1984 Abell New Faculty Research and Graduate Program Award, and also received the 1987/1988 Abell Research Faculty Award. He was declared ‘Researcher of the Year’ by the Colorado State University Research Foundation in 1993. In 2000, he received the Engineering Dean's Council Award from Colorado State University.

He authored a book published by Academic Press entitled ‘Mesoscale meteorological modeling’ in 1984 with a 2nd edition in 2002, a book for Routledge Press entitled ‘The Hurricane in 1990, a book (coauthored with W.R. Cotton) for Cambridge Press entitled ‘Human impacts on weather and climate in 1995; 2nd ed., 2006, a book (coauthored with R.A. Pielke, Jr.) entitled ‘Hurricanes: Their nature and impacts on society’ published in 1997 by John Wiley and Sons, and was co-chief editor (with R.A. Pielke, Jr.) of a book entitled ‘Storms’ published by Routledge Press in 1999.

He was elected as a fellow of the AMS in 1982 and fellow of the American Geophysical Union in 2004. From 1993—96, he served as editor-in-chief of the US National Science Report to the IUGG (1991—94) for the American Geophysical Union. From January 1996 to December 2000, he served as co-chief editor of the *Journal of Atmospheric Science*. In 1998, he received NOAA's ERL Outstanding Scientific Paper (with Conrad Ziegler and Tsengdar Lee) for a modeling study of the convective dryline. He was designated a Pennsylvania State Centennial Fellow in 1996, and named the Pennsylvania State College of Earth and Mineral Sciences Alumni of the year for 1999 (with Bill Cotton). He is currently serving on the AGU Focus Group on Natural Hazards (August 2009—Present) and the AMS Committee on Planned and Inadvertent Weather Modification (October 2009—Present). He is among one of three faculties and one of four members listed by ISI Highly Cited in Geosciences at Colorado State University and the University of Colorado at Boulder, respectively.

He has published over 370 papers in peer-reviewed journals, 55 chapters in books, coedited 9 books, and made over 700 presentations during his career to date. The listing of papers can be viewed at the project website: http://cires.colorado.edu/science/groups/pielke/pubs/. He also launched a science weblog in 2005 to discuss weather and climate issues. This weblog was named one of the 50 most popular Scienceblogs by Nature Magazine on 5 July 2006 and is located at http://pielkeclimatesci.wordpress.com/.

VOLUME EDITORS

Dr Jimmy Adegoke is an award winning climate scientist whose research focuses on understanding the relationships between changing land surface processes and diverse indicators of environmental change. His recent work focuses on societal impacts of environmental change including air pollution studies in rapidly changing midlatitude urban areas and climate impacts on water resources in the Lake Chad Basin. He teaches at the University of Missouri-Kansas City (UMKC) where he served as chair of the Department of Geosciences from 2008—10. From August 2010 until very recently, he was Executive Director of the Council for Scientific and Industrial Research (CSIR) Natural Resources and Environment (NRE) Division, Pretoria, South Africa where he also served as the Director of the Applied Center for Climate and Earth Systems Science (ACCESS), a Center of Excellence (CoE) of the South Africa Department of Science and Technology (DST) Global Change Grand Challenge (GCGC) program. He is a member of several professional societies including the American Geophysical Union (AGU), Association of American Geographers (AAG), and American Meteorological Society (AMS). He is on the advisory council of the African Association for Remote Sensing of the Environment (AARSE) and also serves on the technical advisory committee of several United Nations applied science programs, including the United Nations Educational Scientific and Cultural Organization (UNESCO) crosscutting project on the application of remote sensing for water resources and ecosystem management in Africa. He lives in Kansas city where he served a 3-year team as an appointee of the Mayor of Kansas City Missouri (KCMO) on the city's Environmental Management Commission (EMC).

Dr Caradee Y. Wright is a senior researcher at the Council for Scientific and Industrial Research in the Climate Studies, Modelling and Environmental Health Research Group, leading the environmental health research team. She holds a PhD in public health from the University of Otago and an MSocSc in geography and environmental management from the University of Natal. Her research focuses on personal solar ultraviolet radiation exposure, personal dosimetry, health risk assessment, and skin cancer prevention. Recently, she has also worked in the field of air quality and finding ways to integrate public health into air quality management. She also works in the broader field of environmental health, leading large epidemiological, cross-sectional community surveys to consider the impacts of environmental pollution on community health and appropriate interventions. She is cochair of the South African Young Academy of Science, a member of the Global Young Academy, a council member of the National Association for Clean Air, and founder of the Environmental Health Research Network. In 2012, she was named one of 200 top young South Africans for her efforts to establish a SunSmart Research Programme and Lab in South Africa.

Dr Dev Niyogi is an associate professor with joint appointment in the Departments of Agronomy and Earth, Atmospheric, and Planetary Science at Perdue University.

He is also the State Climatologist for Indiana and Director of the Indiana State Climate Office. His research seeks to advance the understanding of vegetation and land surface processes in environmental, weather forecasting, and climate analyses, using a combination of dynamical models and surface, satellite remote sensing, and multiscale analysis products.

His research deals with the understanding and representation of the effects of vegetation – land surface processes in environmental processes at different scales. He is one of the three invited, nonfederal representatives to the community modeling effort of the Weather Research and Forecast (WRF) model working group on Land Surface Models, and to the Federal Geophysical Data Commission (FGDC) Spatial Climate Working Group.

He has authored or coauthored 25 successful proposals for external grants totaling over $3M. He vertically integrates undergraduate, graduate, and postdoctoral researchers in his research and is very interdisciplinary in developing collaborative projects.

Dr George Kallos is a professor at the University of Athens, School of Physics, Division of Environmental Physics and Meteorology. He leads the Atmospheric Modeling and Weather Forecasting Group (AM & WFG). He has a BSc from the University of Athens/School of Mathematics (1975). He obtained his MSc (1983) and PhD (1985) in Geophysical Sciences/Atmospheric Sciences Division, Georgia Institute of Technology, School of Geophysical Sciences, USA. He has 110 publications in peer review scientific journals, more than 230 presentations and publications in conference proceedings publications, 10 contributions in books and more than 200 other publications in subjects related to atmospheric physics and chemistry, sea-state conditions, and renewable energy production. He has been invited 70 times to give talks in conferences, seminars, etc. His published work has received >2000 citations. He has participated in 80 projects. He has organized 12 conferences related to air pollution and dust transport in the Mediterranean. He has supervised 10 PhDs and over 100 MSc theses and participated in 20 PhD examinations in Greece and Europe. He is an associate editor for the journals: '*Environmental Fluid Mechanics*', '*Advances in Meteorology*', '*International Journal of Geosciences*', '*Atmospheric Pollution Research*', and '*Journal of Aerospace Operations*'. He was awarded the International Union of Air Pollution Prevention Association – IUAPPA award for his work on 'Long-range transport and air quality work in the Mediterranean region'. His current research activities are related to atmospheric, climatic, air pollution, and sea-state model development and forecasting. He focuses in fully coupled modeling systems. The latest model developments are related to nucleation processes in clouds, desert dust cycle and its direct and indirect effects. Research activities related to renewable energy resources (wind, ocean, solar) are focusing on high accuracy atmospheric model development, energy relationships and predictions, and protection from extremes.

Timothy Seastedt received his BA in biology from the University of Montana, an MS degree in biological sciences from the University of Alaska at Fairbanks, and a PhD degree from the University of Georgia. He was on the faculty at Kansas State University and is currently a professor of Ecology and Evolutionary Biology and fellow of INSTAAR at the University of Colorado, Boulder. Much of his research has been conducted as part of the Long-Term Ecological Research (LTER) programs at KSU and CU. His interests focus on terrestrial ecosystem ecology and the causes and consequences of biotic change. His recent activities have emphasized the ongoing changes found along the grassland to (melting) glacier gradient that exists in the Colorado Front Range.

Katharine Suding received her BA in biology from Williams College and a PhD degree from the University of Michigan. She was on the faculty at University of California Irvine and is currently a professor in Environmental Science, Policy and Management at the University of California Berkeley. Her background is in plant community and ecosystem ecology, with current interests in restoration, resilience, and environmental change.

Faisal Hossain received his PhD from the University of Connecticut in 2004. Prior to that, he had earned his MS and BS from the National University of Singapore and Indian Institute of Technology, Varanasi, respectively. He is currently an associate professor in the Department of Civil and Environmental Engineering where he received one of the highest awards of University – the Caplenor Research Award in 2012. His research interests comprise hydrologic remote sensing, uncertainty modeling of water cycle variables, human modification of extreme hydro-climatology, sustainable water resources engineering, space-borne transboundary water resources management, engineering education, and public outreach. He is also the recipient of awards such as NASA Earth System Science Fellowship (2002), Outstanding PhD Thesis Award (2005), NASA New Investigator Award (2008), American Society of Engineering Education (ASEE) Outstanding Research Award (2009), National Association of Environmental Professionals Education Excellence Award (2010), US Fulbright Faculty Award (2012), G.O.L.D. (Graduate Of the Last Decade) award from University of Connecticut (2012), and American Geophysical Union (AGU) Charles Falkenberg Award. He has published over 85 peer-reviewed journal articles, authored an undergraduate-level textbook, edited two book volumes, and contributed eight book chapters. His recent research on human modification of extreme events by artificial reservoirs has been featured by public media such as the BBC, National Geographic, New Scientist, Newsweek, Fox News, MSNBC, Wired.com, and German Public Radio. He served as an associate editor of *Journal of American Water Resources Association* from 2006–10. Currently, he serves as an associate editor for *Journal of Hydrometeorology* and a lead editor for the water volume of Elsevier Sciences five volume reference series on '*Climate Vulnerability: Understanding and Addressing Threats to Essential Resources*'.

PREFACE

We are pleased to introduce the five-volume set of books on bottom-up, resource-based vulnerability assessments of the societally and environmentally key resources of water, food, energy, human health and well-being, and ecosystem function. This inclusive bottom-up vulnerability concept requires the determination of the major threats to these resources from climate, but also from other social and environmental issues. After these threats are identified for each resource, the relative risk from natural- and human-caused climate change (estimated from global climate model (GCM) projections, as well as the historical, paleorecord, and worst case sequences of events) can be compared with other environmental and social risks in order to adopt the optimal mitigation and adaptation strategies.

The bottom-up, resource-based approach (referred to by O'Brien (2009) as 'contextual vulnerability') that is the focus of the volume is distinct from the Intergovernmental Panel on Climate Change (IPCC) top-down assessment of vulnerability based on the multidecadal GCM predictions (projections) which O'Brien defined as 'outcome vulnerability' (**Table 1** and **Figure 1**).

An excellent example of the contextual vulnerability is the paper by Romero-Lankao et al. (2012) who concluded in a study of the literature that urban vulnerability is dominated by epidemiological studies and top-down assessments, but that inherent urban vulnerability and urban resilience approaches (the contextual vulnerability) are what is required in order to illuminate a more complete set of drivers of urban vulnerability. They also showed that the large majority of papers on vulnerability use the outcome vulnerability approach. However, as discussed below, this top-down approach has major flaws.

First, there is the issue that the term 'climate' has two definitions. The broader view (and the one adopted by NRC (2005)) is that climate consists of the atmosphere, oceans, land, and cryosphere. This is the preferred usage. The second definition is that climate is the term used for the long-term (e.g., multidecadal) statistics of weather.

As reported in the NRC (2005) report and written in the Pielke et al. (2009) article with respect to human climate forcings.

> In addition to greenhouse gas emissions, other first-order human climate forcings are important to understanding the future behavior of Earth's climate. These forcings are spatially heterogeneous and include the effect of aerosols on clouds and associated precipitation [e.g., Rosenfeld et al. 2008], the influence of aerosol deposition (e.g., black carbon (soot) [Flanner et al. 2007] and reactive nitrogen [Galloway et al. 2004]), and the role of changes in land use/land cover [e.g., Takata et al. 2009]. Among their effects is their role in altering atmospheric and ocean circulation features away from what they would be in the natural climate system [NRC 2005]. As with CO_2, the lengths of time that they affect the climate are estimated to be on multidecadal timescales and longer.

and

> "…the natural causes of climate variations and changes are important, as are the human influences. The human climate forcings involve a diverse range of first-order climate forcings, including, but not limited to, the human input of carbon dioxide (CO2). Most, if not all, of these human influences on regional and global climate will continue to be of concern during the coming decades."

Threats from climate involve any one or combination of climate variables as illustrated in **Figure 2**. There do not, of course, have to be changes in the statistics of these variables to constitute a risk. The term

Table 1 Contrast between a top-down versus bottom-up assessment of the vulnerability of resources to climate variability and change

Approach	*Comparative vulnerability*	*Contextual vulnerability*
Assumed dominant stress	Climate, recent greenhouse gas emissions to the atmosphere, ocean temperatures, aerosols, etc.	Multiple stresses: climate (historical climate variability, land use and water use, altered disturbance regimes, invasive species, contaminants/pollutants, habitat loss, etc.)
Usual timeframe of concern	Long-term, doubled CO_2 30–100 years in the future.	Short-term (0–30 years) and long-term research.
Usual scale of concern	Global, sometimes regional. Local scale needs downscaling techniques. However, there is little evidence to suggest that present models provide realistic, accurate, or precise climate scenarios at local or regional scales.	Local, regional, national, and global scales.
Major parameters of concern	Spatially averaged changes in mean temperatures and precipitation in fairly large grid cells with some regional scenarios for drought.	Potential extreme values in multiple parameters (temperature, precipitations, frost-free days) and additional focus on extreme events (floods, fires, droughts, etc.) measures of uncertainty.
Major limitations for developing coping strategies	Focus on single stress limits preparedness for other stresses. Results often show gradual ramping of climate change-limiting preparedness for extreme events. Results represent only a limited subset of all likely future outcomes – usually unidirectional trends. Results are accepted by many scientists, the media, and the public as actual 'predictions'. Lost in the translation of results is that all models of the distant future have unstated (presently unknowable) levels of certainty or probability.	Approach requires detailed data on multiple stresses and their interactions at local, regional, national, and global scales, and many areas lack adequate information. Emphasis on short-term issues may limit preparedness for abrupt "threshold" changes in climate sometime in the short or long term. Requires preparedness for a far greater variation of possible futures, including abrupt changes in any direction – this is probably more realistic, yet difficult.

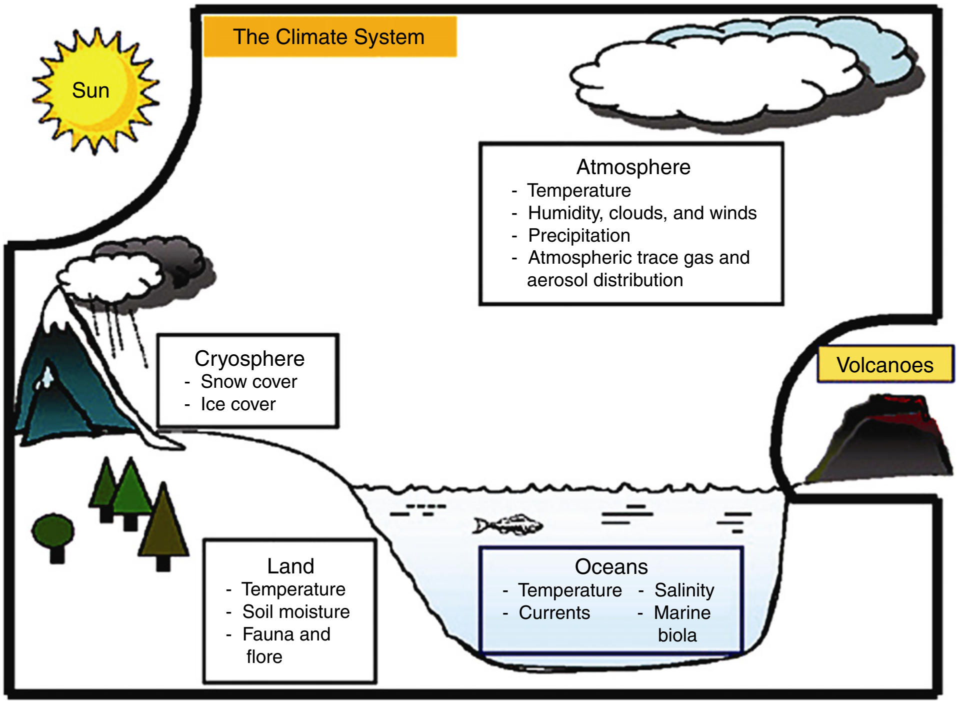
Figure 1 Framework depicting two interpretations of vulnerability to climate change: (a) outcome vulnerability and (b) contextual vulnerability. *From: Füssel (2009) and O'Brien et al. (2007).*

'climate change' should be used to describe any multidecadal or longer alteration in one or more physical, chemical, and/or biological components of the climate system, but as explained below, this terminology has morphed into multiple, diverse (and often mutually exclusive) definitions as used by the impacts communities.



The Climate System
Sun
Atmosphere
- Temperature
- Humidity, clouds, and winds
- Precipitation
- Atmospheric trace gas and aerosol distribution
Cryosphere
- Snow cover
- Ice cover
Volcanoes
Land
- Temperature
- Soil moisture
- Fauna and flore
Oceans
- Temperature
- Currents
- Salinity
- Marine biola

Figure 2 The climate system, consisting of the atmosphere, oceans, land, and cryosphere. Important state variables for each sphere of the climate system are listed in the boxes. For the purposes of this report, the Sun, volcanic emissions, and human-caused emissions of greenhouse gases and changes to the land surface are considered external to the climate system (NRC 2005).

First, climate is never static (Lovejoy and Schertzer 2012). As written in Rial et al. (2004)

> "The Earth's climate system is highly nonlinear: inputs and outputs are not proportional, change is often episodic and abrupt, rather than slow and gradual, and multiple equilibria are the norm."

The assumption of a stable climate system (e.g., the reason for the use of the terminology 'climate stabilization') in the absence of human intervention is a mischaracterization of the behavior of the real climate system. Humans are now adding to the complexity of forcings and feedbacks, but change has always been a part of the climate system. 'Climate change' is, and always has, been occurring. The added word 'change' is, therefore, redundant.

Moreover, there are additional misunderstandings. 'Global warming', which is an increase in the global annual average heat content measured in Joules, is often incorrectly equated to mean 'climate change'. Global warming, however, is just a subset of "climate change."

The term 'climate change', is also being erroneously used to mean only 'anthropogenic caused changes in climate' from nearly 'static' climatic conditions. Frequently, just the human input of greenhouse gases is assumed to be the reason for 'climate change'. For example, NRC (2010) (Climate Stabilization Targets: Emissions, Concentrations, and Impacts Over Decades to Millennia (2010)) states

> "This new report from the National Research Council concludes that emissions of carbon dioxide from the burning of fossil fuels have ushered in a new epoch where human activities will largely determine the evolution of Earth's climate."

Thus, the recommendations to the authors of the volume (not always accepted) were to replace terminology, such as climate change, climate stabilization, and climate disruption, with accurate terminology. When changes in climatic conditions are discussed, it was requested that the actual climate variables (such as temperature, precipitation, length of growing season) that are being altered, be specified. Phrases such as 'changes in regional and global climate statistics' could also be used.

There is a very fundamental reason to limit the use of ‘climate change’ by the impacts community. Key societal and environmental resources, such as water, food, energy, ecosystem function, and human health respond to climate, not just to an incremental change in the climatic conditions. As noted earlier, the assumption of a stable climate system, in the absence of human intervention, is a mischaracterization of the behavior of the real climate system.

However, some authors retained the use of the terminology ‘climate change’. It was acquiesced as long as there was a significant contribution in their chapter to a broad-based assessment of risk to the key resource they were discussing.

Another misused term is ‘global change’, when really what is almost always meant is a local and/or regional change in the environmental conditions, including from climate. The accurate terminology should be ‘environmental change’. The term ‘environmental change’ is, therefore, preferred rather than ‘global change’, as the latter terminology is very much a top-down viewpoint. Almost all impacts on key resources are on the local and regional scale.

We also requested the authors start with the risks and factor in the climate threats after thresholds, etc. were first obtained. This was not done in some chapters, but this information can still be extracted from the text. Obtaining the spectrum of risks first is the more inclusive way to assess threats to key resources, and thus, in the view, to prepare the optimal mitigation and adaptation strategies.

For the climate component of risk, the outcome vulnerability (the top-down) approach relies on skillful weather predictions and analyzes with a regional and a local focus. For weather prediction on time periods of days to a week or two, excellent skillful predictions are available for use in outcome vulnerability assessments. On seasonal timescales, there is also some limited predictive skill to apply to outcome vulnerability assessments, particularly for such well-defined weather events such as an El Niño or La Niña (Castro et al. 2007). However, for decadal and multidecadal predictions little, if any, predictive skill has been shown in hindcast climate model predictions of changes in regional weather statistics beyond what is available to the impacts community via the historical, recent paleorecord and a worst case sequence of weather events.

To illustrate the lack of skill, the conclusions from several papers have been summarized. Fyfe et al. (2011) concluded that

> “….for longer term decadal hindcasts a linear trend correction may be required if the model does not reproduce long-term trends. For this reason, we correct for systematic long-term trend biases.”

Xu and Yang (2012) find that without tuning from real world observations, the model predictions are in significant error. For example, they found that

> …the traditional dynamic downscaling (TDD) [i.e. without tuning) overestimates precipitation by 0.5-1.5 mm d-1…..The 2-year return level of summer daily maximum temperature simulated by the TDD is underestimated by 2-6°C over the central United States-Canada region."

The paper van Oldenborgh et al. (2012) report just limited predictive skill in two regions of the oceans on the decadal time period, but no regional skill elsewhere, when they conclude that:

> "A 4-model 12-member ensemble of 10-yr hindcasts has been analysed for skill in SST, 2m temperature and precipitation. The main source of skill in temperature is the trend, which is primarily forced by greenhouse gases and aerosols. This trend contributes almost everywhere to the skill. Variation in the global mean temperature around the trend does not have any skill beyond the first year. However, regionally there appears to be skill beyond the trend in the two areas of well-known low-frequency variability: SST in parts of the North Atlantic and Pacific Oceans is predicted better than persistence. A comparison with the CMIP3 ensemble shows that the skill in the northern North Atlantic and eastern Pacific is most likely due to the initialisation, whereas the skill in the subtropical North Atlantic and western North Pacific are probably due to the forcing."

Anagnostopoulos et al. (2010) report that

> "…. local projections do not correlate well with observed measurements. Furthermore, we found that the correlation at a large spatial scale, i.e. the contiguous USA, is worse than [even] at the local scale."

Stephens et al. (2010) wrote

> "models produce precipitation approximately twice as often as that observed and make rainfall far too lightly…..The differences in the character of model precipitation are systemic and have a number of important implications for modeling the coupled Earth system …….little skill in precipitation [is] calculated at individual grid points, and thus applications involving downscaling of grid point precipitation to yet even finer-scale resolution has little foundation and relevance to the real Earth system."

van Haren et al. (2012) concluded from their study with respect to climate model predictions of precipitation that

> "An investigation of precipitation trends in two multi-model ensembles including both global and regional climate models shows that these models fail to reproduce the observed trends….. A quantitative understanding of the causes of these trends is needed so that climate model based projections of future climate can be corrected for these precipitation trend biases…. To conclude, modeled atmospheric circulation and SST trends over the past century are significantly different from the observed ones."

Sun et al. (2012) found that

> "…in global climate models, [t]he radiation sampling error due to infrequent radiation calculations is investigated …….. It is found that…. errors are very large, exceeding 800 W m^{-2} at many non-radiation time steps due to ignoring the effects of clouds…."

There is an important summary of the limitations in multidecadal regional climate predictions in Kundzewicz and Stakhiv (2010) who succinctly conclude that

> "Simply put, the current suite of climate models were not developed to provide the level of accuracy required for adaptation-type analysis."

Since the top-down outcome vulnerability approach depends on skillful decadal and longer regional and local climate predictions, yet they have shown little if any skill, another approach is needed.

For this reason, the volume set of five books presents an alternate approach – the bottom-up, resource-based outcome (contextual) vulnerability perspective. The goal of the set was to focus on the climate component of stress but also consider, in-depth, other environmental and social threats.

The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the respective field.

The questions requested to the authors address with respect to a specific resource were:

1. Why is this resource important? How is it used? To what stakeholders is it valuable?
2. What are the key environmental and social variables that influence this resource?
3. What is the sensitivity of this resource to changes in each of these key variables? This includes, but is not limited to, the sensitivity of the resource to climate variations and change on short (e.g., days), medium (e.g., seasons), and long (e.g., multidecadal) timescales.
4. What changes (thresholds) in these key variables would have to occur to result in a negative (or positive) response to this resource?
5. What are the best estimates of the probabilities for these changes to occur? What tools are available to quantify the effect of these changes? Can these estimates be skillfully predicted?
6. What actions (adaptation/mitigation) can be undertaken in order to minimize or eliminate the negative consequences of these changes (or to optimize a positive response)?
7. What are specific recommendations for policymakers and other stakeholders?

There are also overview chapters that discuss the science of the resource.

Several authors insisted on focusing on the use of the outcome vulnerability (top-down) approach based on the multidecadal GCM projections (statistically or dynamically downscaled) as the starting point of their chapters. The chapters were accepted, despite this shortcoming, because when they finally discussed adaptation in their text, they did present the broader-based bottom-up focus that is the centerpiece of the volume. Readers,

however, need to be aware that the top-down, GCM scenarios are only a subset, at best, of what is plausible in the coming decades. Multidecadal predictions of changes in regional and local climate statistics have not shown skill when run in a hindcast mode for the past several decades.

In summary, the goal of the five-volume set of books is to document the value of a bottom-up, resource-based assessment of risk to key resources, as illustrated schematically in Figure 3a–e. Most, but not all, authors accepted this framework. This can be assessed without having any predictability on

multidecadal time periods. It is an alternative (and more inclusive) perspective than the IPCC top-down outcome vulnerability approach which starts with the GCMs as the overarching framework. In the bottom-up approach, the scenarios from the GCM predictions should only enter after the specific threats to the resources are determined and even then, they provide, at best, a limited set of insights into what is possible.

Preface - Vulnerability of Water Resources to Climate

F Hossain, Department of Civil and Environmental Engineering, Tennessee Technological University, Cookeville, TN, USA

© 2013 Elsevier Inc. All rights reserved.

No matter how differently we all prefer to classify the key resources for the human civilization and the health of our planet, water will always remain a common denominator. In fact, one could argue that water is most intimately linked as a resource with other key resources such as human health (imagine cholera, malaria, or sanitation), food (imagine the green revolution to feed a hungry population), energy (about 10% of the world's energy is generated from hydropower), and ecosystem function (where water availability dictates the type of flora and fauna). Perhaps no other resource is as important to so many other resources or is as starkly dependent on so many other resources.

Like the other volumes of the climate encyclopedia, the volume on water was compiled with the mindset that understanding the vulnerabilities facing our water resources today requires a very bottom–up or contextual approach that is missing in today's literature. After all, it is this contextual approach that a stakeholder can use for adaptation or decision making at the local scale. Thus, this volume, like the encyclopedia overall, makes a very conscious attempt to move away from the plethora of top–down and outcome-oriented vulnerability assessment studies available at present. Instead, the volume presents an alternative but more actionable view of water as a resource. It asks the following questions:

- What are the key issues or threats facing the availability of water resources today?
- How do we use the understanding of these issues to make the health of our planet and human civilization more resilient in the near future?

Since the 'near future' is a key focus, this volume wholeheartedly avoids assessments based purely on the commonly studied 50- or 100-year emission-driven scenarios of future climate. The more pressing question for local stakeholders is:

- "What do we need to do right now so that we can do an even better job in the future in maintaining a resilient civilization in our region?"

This volume is designed for both the busy reader needing specific information for an action-oriented agenda and the more diligent student wishing to build a comprehensive theoretical background on water resources vulnerability. The volume is divided into two sections. The first section presents a series of 10 chapters that covers the 'state-of-the-art' theory on our physical understanding of water resources variability. The second section presents 15 region-specific case studies on the characterization of water resources vulnerability and the lessons that we have learned so far, which of course, is very contextual. Thus, the more conscientious reader should read the entire volume systematically, beginning with the very convincing overview of the concept of contextual vulnerability assessment by Bloeschl et al. This is followed by a synopsis of the best estimate of the quantity of water we have in this world today by Balazs Fekete. Precipitation often mirrors the available water as a resource. The human civilization has had to devise numerous infrastructures (dams, channels, urban drainage, irrigation schemes, reservoirs, etc.) to deal with the extremes of water availability, which are difficult to adapt to. The third chapter by Groisman et al. therefore provides a synopsis on what the observations tell us now about precipitation extremes around the world. The two chapters in this section deal specifically with mountains, which often function as a 'funnel' to trap atmospheric moisture in a form that is more usable as a resource. Ana Barros presents an overview of our current understanding of the physics of this moisture entrapment and precipitation in mountainous regions (Chapter 5.4). Deepak Ray presents the state of the art on very sensitive ecosystems that are located high up in the mountains of the tropics (called tropical montane cloud forests) in select regions of the world (Chapter 5.5). Authors Marshall Shepherd and Burian et al. present a detailed rendition of the impact of urban infrastructure on climate (particularly precipitation) and the implications on sustainability of city centers, respectively. Analysis of paleoclimate data is considered essential in any contextual vulnerability assessment and for verifying the attribution of potential human contribution to the current or future state of water availability. Rashid et al. provide a very timely chapter entirely on the use of paleoclimate data to understand abrupt climate change. Finally, the last two chapters of the first section provide a view of what is to come in the future for measurement, monitoring, and vulnerability assessment. Space-borne sensors are becoming increasingly cost effective and accurate in detecting the changes in water fluxes in difficult-to-access regions. Two particular types of satellites are considered in this volume – passive sensors that can estimate precipitation (Chapter 5.9) and geodetic sensors that can measure changes in gravimetry (Chapter 5.10) that are often dictated by changes in terrestrial water storage.

The next section (Section 2) provides a series of 15 case studies by region, such as the Arctic, North America, Andes, China, East and West Africa, Sahara, South Asia, and Europe. These chapters may be read as stand-alone contributions by the busy reader if desired. However, the chapters are organized per region or theme so that continuity is not lost when moving from one chapter to the next. Several of the chapters have themes that cut across to another volume. For example, the chapter by Akanda et al. on the role of hydrology on cholera in the Bengal Delta (Chapter 5.22) will be found to be highly relevant to the volume on Human Health. Similarly, the chapter by Wood et al. on the sustainability of hydropower (Chapter 5.12) relates closely to the volume on Energy.

Other than the invaluable services of the editor-in-chief (Roger Pielke Sr.) and the 'always-available' Elsevier support staff, this volume would not have been possible without the selfless peer service of the many reviewers who helped ensure quality of each published chapter. In particular, we would like to acknowledge the following people who spent countless hours going methodically through the chapters to improve its

http://dx.doi.org/10.1016/B978-0-12-384703-4.00541-4

content: Michael Durand, Hatim Sharif, Jonathan Gourley, Marloes Bakker, Eric Rosenberg, Matthew Cohen, Holger Hoff, Alfred Kalyanapu, Steve Burian, Qingyun Duan, Mervin Peart, Petra Dam, Hyongki Lee, James Voogt, Nathalie Voisin, Tamlin Pavelsky, Shuhab Khan, John Fazio, and many others who have wished to remain anonymous.

We are poised delicately in the twenty-first century where water as a resource will play an increasingly more critical role for human civilization and the health of our planet. To make the best use of this precious resource and understand its impact or implication of use, we need knowledge *now* at a scale practically relevant for decision making and adaptation. This volume aims to achieve just that through a collection of 25 chapters by leading authorities. It is our hope that this volume can provide the most actionable knowledge on water resources for the vast community of busy stakeholders, policy planners, and the engaged student looking for education appropriate for the twenty-first century.

5.01 Emerging Approaches to Hydrological Risk Management in a Changing World

5.01.1 Unexpected Events and Risk Management

7 August 1994. The township of Tirlyan in the Republic of Bashkortostan, Russia. The dam operators are at the verge of panicking. There had been major rainfalls on the previous days and the water level of the Tirlyan reservoir had been increasing steadily during the day. While the dam was relatively small with 10 m height, the volume was 8.6 million cubic meters and posed considerable danger for the downstream villages of Tirlyan, Avzalovo, Kazylyarovo, and Alakagovo. One of the segment gates had been blocked years before because of concerns about sabotage, and the operators were hectically attempting to release the gate. No way that the remaining gates would be able to cope with the floodwaters. 16:20. The gate is still blocked and the water levels have reached the top of the dam – an earth fill dam constructed in 1917. Villagers have flocked to the banks of the Belaja river downstream of the dam to watch the spectacle. Minutes later, the water of the reservoir starts to overtop the dam. A breach forms and a wide section of the dam gives way. The flood wave spills over the downstream plain and gets hold of dozens of bystanders. The spectacle had turned into a disaster. Many people can be saved, but the flood takes its death toll among the villagers (Moscow News, 19 August 1994).

Avoiding events like this is one of the main purposes of hydrological risk management. In hindsight, the cause of the failure was almost trivial. With a little more lead time, it would have been easy to open the gate and avoid the disaster. Also, it was not a design problem. It was a contingency none of the dam operators had foreseen.

Society is becoming increasingly aware of the risks associated with hydrologic extremes, in particular floods and droughts. With climate being high on the political agenda, it is clear that the links between climate and hydrological risks have become a major concern for politicians, flood managers, and citizens alike. There is a debate on whether there have been climate-related increases in the severity and frequency of floods and droughts in the past decades. While numerous devastating floods and droughts have occurred recently, it has been argued that confirmation bias could play a role in the attribution to causes, that is, the tendency to favor information that confirms existing preconceptions (Taleb 2007; Merz et al. 2012). Increases in damage may be more related to socioeconomic change than to hydrologic change (Di Baldassarre et al. 2010; Bouwer 2011). In a particular catchment, extremes may or may not have increased but the fact remains that there is an urgent need for managing hydrological risks in the best possible way. Many countries have passed new legislation such as the EU Flood directive (EU 2007) that explicitly requires the establishment of flood risk management plans. There are similar drought risk management plans in a number of countries and states (e.g., Jacobs et al. 2005). The concept of integrated hydrological risk management (IHRM) (for both floods and droughts) is currently implemented widely.

Fundamental to the concept of risk are the notions of hazard and vulnerability, which both contribute to the risk. Hazard relates to a dangerous phenomenon (flood or drought), human activity (river damming), or condition (water scarcity) that may cause societal disruption or environmental damage (see the Hyogo Framework for Action, UN-ISDR 2005), whereas vulnerability relates to the characteristics of the people, the property, or the environment that are at risk. If one is to manage risks one can try to manipulate the hazard, the vulnerability, or both. Figure 1 shows the 2005 flood in Tirol, Austria. Clearly, the risk is high because of the presence of the houses. This is a vulnerability problem.

Given the recent and expected future changes in the water-related environment, developing strategies of hydrological risk management and implementing them pose a number of challenges. In this chapter, we will discuss the methods that can be used in IHRM and review emerging approaches of how to prioritize the implementation of these methods.

5.01.2 Elements of Integrated Hydrological Risk Management

The hallmark of IHRM is that a variety of actions are considered and implemented in an integrated way. This sets IHRM

http://dx.doi.org/10.1016/B978-0-12-384703-4.00505-0

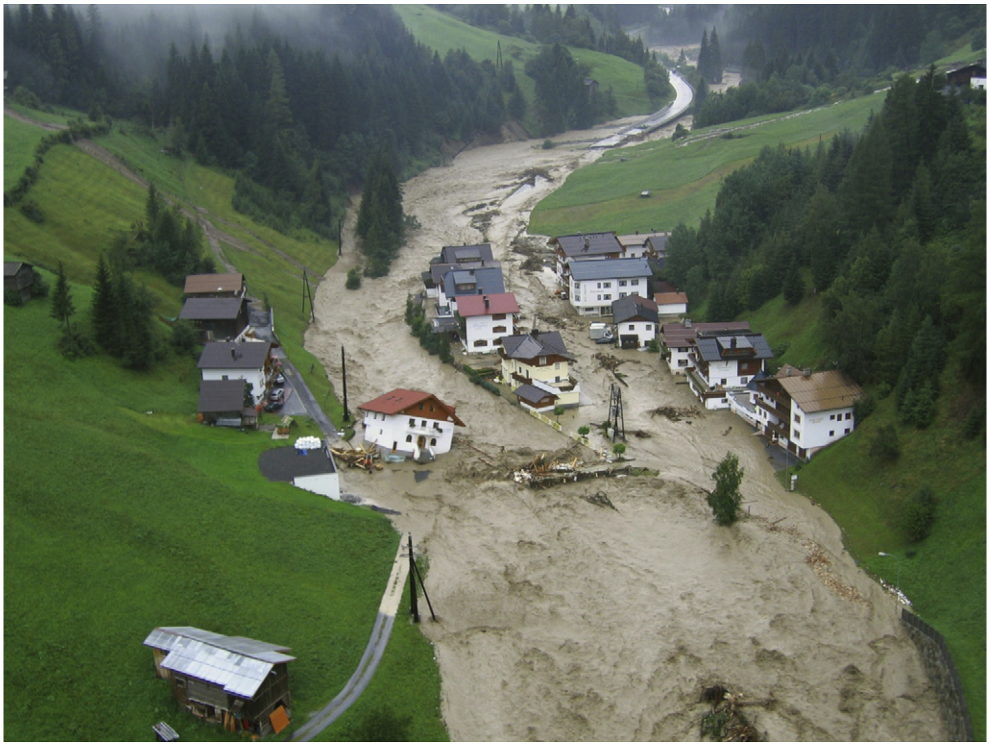

Figure 1 August 2005 flood in Tirol Austria. Only a few decades ago, when there was not a single building at this location of the valley, a similar flood would not have been considered a disaster.

apart from traditional flood protection (and drought abatement) where individual measures were considered in isolation and sometimes the focus was on structural measures (such as dams) alone. Conceptually, the possible measures (or actions) are usually arranged along a hypothetical time axis of the disaster risk cycle that consists of four phases: mitigation, preparedness, response, and recovery (e.g., Thieken et al. 2007). In the case of flood risk management, mitigation involves a range of structural measures to reduce hazard and/or vulnerability, such as dams, levees for flood protection, polders of flood mitigations, and nonstructural measures such as land use zoning and insurances. Preparedness involves the establishment of emergency plans, the training of flood management staff, awareness building of the general public, and issuing flood warnings. Response involves immediate actions for protecting life and property such as evacuations and the provision of food and shelter. Recovery involves longer-term responses such as cleanup and rebuilding of structures. Preparedness, response, and recovery aim to reduce vulnerability. Nonstructural measures can be highly efficient. For example, the 2002 flood in the Czech Republic led to a much smaller number of flood-related fatalities than the 1997 flood, although it was larger. This was a result of the increased flood awareness and preparedness (Di Baldassarre et al. 2010). A similar cycle with a diversified mix of measures applies to drought risk management (UNDP 2011) but the time scales tend to be longer because of the more long-term nature of droughts.

The relative efficiency and effectiveness of individual measures depend on the local conditions (Samuels et al. 2010; Borga et al. 2011). Because of this, prioritizing the measures is difficult, particularly given the recent changes in demography, economy, assets, land use, and climate as they all contribute to the risk (Hooijer et al. 2004; Thomalla et al. 2006; Birkmann and von Teichman 2010; Etkin et al. 2011; Solecki et al. 2011). There are two approaches of addressing the prioritization of risk management measures (Figure 2).

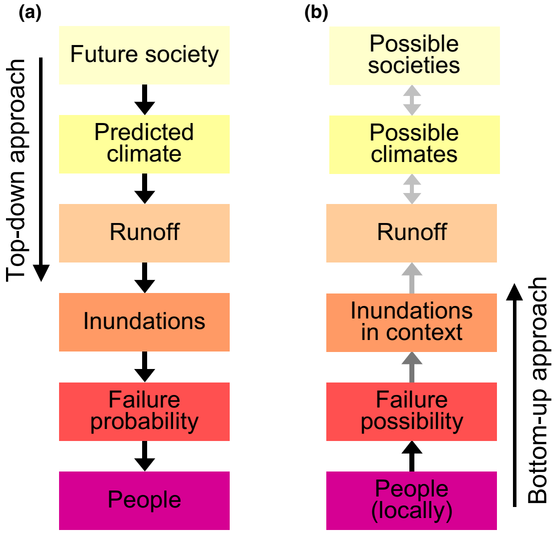

Figure 2 (a) Traditional top-down approach to hydrological risk assessment based on climate projections. (b) Bottom-up approach to hydrological risk assessment that is vulnerability or resilience centered. Approaches are illustrated by a fluvial flood risk example. Gray arrows indicate less dependence than black arrows.

The first, termed the top-down approach, starts from the climate forcing, cascading down information to the people affected by the floods or droughts. The second, termed bottom-up approach, starts from the people affected and explores possibilities of risk management (Dessai et al. 2009a,b; Wilby and Dessai 2010). These two approaches are discussed in the two next sections.

5.01.3 Top-Down (Economic) Approach to Risk Assessment Based on Probabilities

The 'top-down' approach is designed to represent the main processes causing the hazard and its consequences. In the case of climate impacts on floods (Figure 2), the 'top-down' approach starts at the global scale and cascades information from emission scenarios of future societies to simulated climates using global and regional climate models, to runoff using hydrological models, to inundations using hydrodynamic models, and to damage costs using economic models. The top-down approach is motivated by an economic paradigm. Hence, risk is defined from an economic perspective, specifying hazard as the occurrence probability of a flood (or drought) event, vulnerability as the damage cost in monetary terms, and (economic) risk as the product of the two. This leads to an optimization problem that aims at identifying the most economic management strategy among those discussed in the previous section.

The 'top-down' approach is the most widely used approach for impact and adaptation assessments (Blöschl et al. 2007). The 'top-down' approach is sometimes termed the 'predict-then-act' method as projected scenarios are the starting point and the main emphasis (Dessai and Hulme 2004). Scenarios differ in terms of the global development (affecting greenhouse gas emissions and simulated climate) and in terms of local development such as agricultural development, urbanization, construction of infrastructure, and other human activities (Kundzewicz et al. 2002; Wilby et al. 2009). The entire cascade is rigorously model based. Often, the scenario analysis is complemented by narrative descriptions of multiple facets of possible futures to ensure internal consistency (Merz et al. 2010). Applications of the top-down approach to hydrological risk assessment abound (e.g., Johnson and Weaver 2009; Lugeri et al. 2010; Veijalainen et al. 2010), many of which have an explicit focus on economics (e.g., Aerts and Botzen 2011; Zhou et al. 2012).

The appeal of the top-down approach is that it is conceptually straightforward and elegant as it mimics what is considered the main process cascade. Two questions arise: (1) should minimizing costs be the main societal goal and (2) is it possible to quantify future hazards and vulnerabilities to the accuracy needed?

1. Societal goals must, of course, be set in a political discourse. Surprisingly, there is relatively little open debate on this in hydrological risk management. Although the economic paradigm seems to be the most frequently adopted today, in practice, risk management measures often depart from it, even if the IHRM in a particular catchment is set in an (economic) risk framework. This is illustrated by examples from fluvial flood management: Emergency actions such as evacuations are rarely based on cost/benefit considerations but on (social) humanitarian goals. Also, when prioritizing flood defense structures, often, worst-case scenarios that are at variance with the economic optimality goal are considered. Since extreme floods are usually economically less important than smaller floods if a long period is considered (Merz et al. 2009), risk aversion functions can be used to give greater weight to extreme events (Merz et al. 2010), which again deviates from the economic optimality goal toward a more social perspective. Similarly, in issuing flood warnings, maintaining credibility is often of higher priority to the flood warning staff than economic optimality (Blöschl 2008). A more explicit debate on the goals of IHRM in a changing world would be desirable.
2. The accuracy of quantifying future hazards and vulnerabilities has received more attention. Each modeling step of the top-down approach (Figure 2) introduces uncertainties that may lead to different prioritizations of risk management measures, depending on the assumptions made, and in fact to ineffective risk management (van Pelt and Swart 2011). The concept of economic risk hinges on the interpretation of the hazard as a probability. However, it may not be possible to specify such probabilities because of the nature of the socioeconomic processes (Grübler and Nakicenovic 2001). There are therefore two schools of thought in the top-down approach (Dessai and Hulme 2004). The first rigorously defines probabilities of, say, future droughts for estimating the risk. The second interprets scenarios as possible future developments, so the probabilities are more vaguely defined. Another dilemma is that, per definition, one is interested in conditions that are different from the past (in some ways), so testing the models of the cascade to past data does not fully confirm their credibility. Many Earth scientists hold a positivistic world view that assumes that, if enough data are analyzed in the right way, one can understand and resolve even the most complex problems, so the line of thought is that more detailed models will solve the dilemma. Hydrology has a long history of scientific discourse about the primacy of the reductionist (process-based or Newtonian) world view or the alternative holistic (data-based or Darwinian) world view (e.g., Sivapalan 2003; Savenije 2009; Merz et al. 2011). Figure 3 illustrates the point. Assume that we were in the year 1900 and had today's complex process models and computing power. Even with these it would be essentially impossible to predict the evolution of floods in the twentieth century for the Danube. The broader discussion in hydrology suggests that in many instances reductionist approaches are needed for identifying causal links, but there are many cases of societal relevance where feedbacks and emerging patterns make the reductionist approach questionable, so more holistic approaches should be preferred (Peel and Blöschl 2011; Blöschl and Montanari 2010). Similar arguments have been forwarded in Earth System modeling, in particular at the interface between socioeconomic and biophysical processes (Pielke 2004; Koutsoyiannis et al. 2009; Wilby and Dessai 2010; Sivapalan et al. 2012).

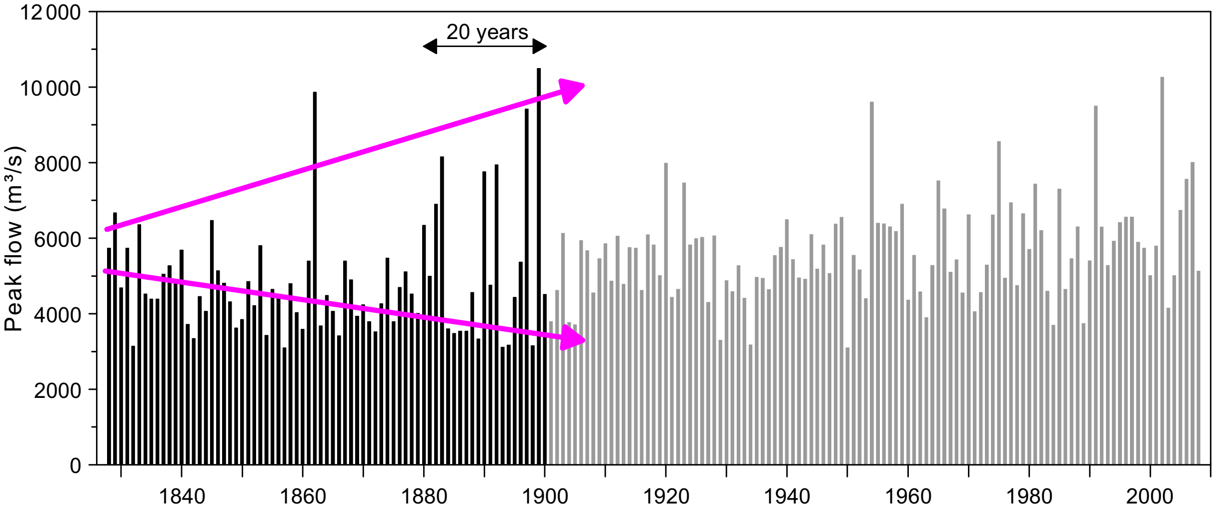

Figure 3 Maximum annual floods of the Danube at Vienna. Based on the data 1828–1900 (highlighted in black) it would be essentially impossible to predict the evolution of floods in the twentieth century for the Danube even if today's complex process models and computing power were available. Pink arrows indicate possible evolutions of large and small floods. Modified from Blöschl and Montanari (2010).

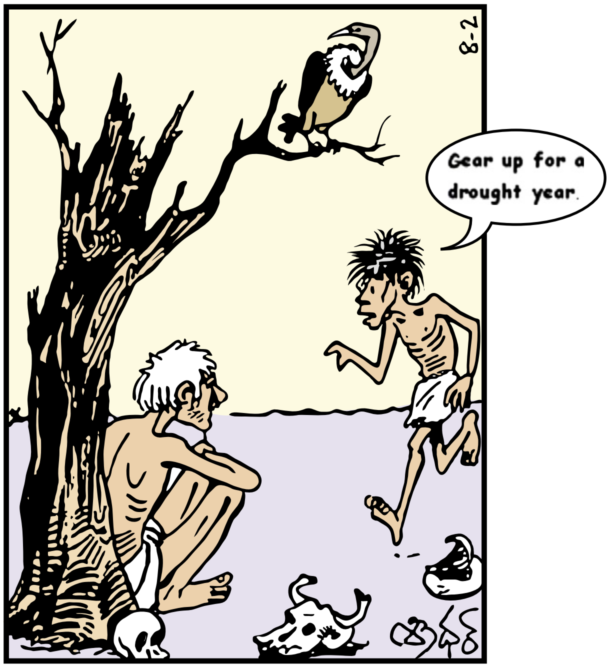
One way of addressing the uncertainty dilemma is to perform probabilistic uncertainty analyses (Dessai and Hulme 2004). Emerging methods represent the uncertainty of the hazards and/or vulnerabilites by Ensemble (Monte Carlo) methods while keeping a process-based approach that allows one to profit from available process knowledge. A number of recent studies have demonstrated the feasibility of this approach for the case of inundations due to fluvial floods (e.g., Apel et al. 2004; Di Baldassarre et al. 2009; Merz et al. 2010). By recognizing randomness and uncertainty, such a framework does not yield deterministic predictions, but the uncertainty estimates can be very useful. Extending these probabilistic uncertainty frameworks to a range of processes relevant to hydrological risk management has, *inter alia*, been proposed by Koutsoyiannis et al. (2009) and Blöschl and Montanari (2010), and Wetterhall et al. (2011) presents a study of probabilistic uncertainty analyses of hydrological risk in Sweden.

5.01.4 Bottom-Up (Social) Approach to Risk Assessment Based on Possibilities

The 'bottom–up' approach (Figure 2) starts at the local scale of individuals, households, and communities and explores the factors and conditions that enable successful coping with hydrological extremes (Wilby and Dessai 2010). The bottom-up approach is motivated by a social paradigm. Hence, risk is not defined in monetary but in more qualitative terms. The main goal is not to find the most economic management strategy but to ensure the well-being of people by reducing vulnerability and enhancing resilience (the ability to recover after an event). It does not take climate projections as a starting point but the vulnerability and resilience of the risk-related system itself (van Pelt and Swart 2011). It is sometimes termed the 'assess-risk-of-policy' method as it explores alternative policies first.

Although the top-down approach is currently more popular, realization of the importance of the bottom-up approach is emerging: *"Society will even benefit much more from a greater understanding of the vulnerability of climate-influenced decisions to large irreducible uncertainties than it will from extremely expensive attempts to increase the accuracy and precision of climate predictions. An alternative approach to the conventional one based on climate prediction would therefore focus on exploring how well strategies perform across wide ranges of assumptions and uncertainties (Robust Adaptation Decision-Making)."* (European Commission 2009, p. 13).

The bottom-up approach differs from the top-down in that the main aim is to reduce vulnerability and enhance resilience. It has therefore particular value in countries in which the vulnerabilities to floods and droughts tend to be high such as in the developing world (Di Baldassarre et al. 2010; UNDP 2011). Also, it may be more ethically justified as it puts people center stage. Typically, the strategies are not optimal from an economical perspective but they are robust, that is, they are designed to perform well over a wide range of assumptions about the future and potentially extremely negative effects. In other words, they are 'low-regret' strategies. Note that 'no-regret' strategies do not exist in any kind of nontrivial decision making. Since the starting point is local communities, they tend to be more creative and inclusive of a broader range of information, such as governance and lessons learned from the past and other catchments, context-dependent information, contingencies, and narratives (Pielke 2004). Clearly, the Tirlyan disaster could not have been anticipated by a top-down risk approach. It may have been possible to speculate in advance about the possibilities of blocking the gate based on *local* experience, but this is not a type of information that can enter into a formal optimization analysis. The bottom-up approach is therefore based on 'possibilities' rather than on probabilities. Because of this, it tends to be less dependence on probabilities inferred from the predictive scenario approach (Sarewitz et al. 2003). The preference for alternative strategies may become



8-2
Gear up for a drought year.

Figure 4 Drought predictions, however accurate, delivered by the young man are completely useless to the old man because of his high vulnerability. The course of action is clear; the actions just need to be done. [Available online at http://sriks6711.wordpress.com/2009/08/03/india-is-drought-hit-in-2009.]

insensitive to the assumptions of climate scenarios since other factors (including local socioeconomic factors) dominate, but this will depend on the local setting. This is a notion that Prudhomme et al. (2010) term 'scenario-neutral'. In Figure 2, the weaker sensitivity (or lack of sensitivity) to the scenario predictions is indicated by the gray arrows. Local information on the social characteristics related to floods and droughts may indeed be more relevant than global predictions. Consider the cartoon in Figure 4. It appears that the drought predictions, however accurate, delivered by the young man are completely useless to the old man sitting by the tree because of his high vulnerability and the lack of options he has. The point of the bottom-up approach is that scenario predictions are not helpful for deciding how to improve the fate of the people in the cartoon. The course of action needed is clear; the actions just need to be done.

However, the pros of the bottom-up approach come at an expense. It is significantly more 'messy' and lacks the conceptual elegance of the top-down approach. The most relevant consequence is a more difficult interaction with stakeholders. As a matter of fact, the effort to explore what the future will be looks more appealing than a seemingly unstructured analysis of the present. Indeed, vulnerability is determined by a host of factors including variations in wealth, social equality, food availability, health and education status, physical and institutional infrastructure, access to natural resources, and technology (Wilby and Dessai 2010) that condition the analysis and prevent to set up a unified framework for the bottom-up approach. Also, the methods tend to be more messy, as is often the case in the social sciences (see, e.g., the evaluation of participative methods in water resources, Carr et al. 2012). Methods often involve exploratory modeling approaches in which multiple runs of simulation models are used to systematically explore the implications of a wide range of assumptions and contingencies (Dessai et al. 2009a). These assist in making policy arguments. An important role is played by historical data in the case study or similar catchments. Equally important, a range of methods from the social sciences are used, such as surveys, impact diagrams, mind maps, causal loop methods, and visualization methods involving the local risk managers and stakeholders (e.g., UNDP 2011; Waser et al. 2010), to explore the perceived or real causal structure of the system.

Since the problem is messy, case studies play an important role. The vulnerability approach of Simonovic (2010), for example, starts from analyzing existing policies and management practices in a Canadian catchment with respect to critical flood and drought situations, which he then transforms into corresponding critical meteorological conditions. Schelfaut et al. (2011) focus on enhancing the resilience by identifying the opportunities and bottlenecks of flood risk management in a number of European catchments, such as institutional interplay, flood management tools, and risk communication. For a flood risk case study of the river Rhine van Pelt and Swart (2011) conclude "*The 'assess-risk-of-policy' approach recognizes local interests and conditions, and offers possibilities to deal with uncertainties that cannot be quantified, by focusing on the resilience of the system. First results of this method show that it can offer policy makers a new, complementary tool for evaluating adaptation strategies that also addresses their non-climate priorities and maybe [provides] a different view on the urgency of adaptation to climate change.*" In Southern Austria, experience with the 2003 drought was used to assess the vulnerability of the water supply system and to enhance the connectivity of the infrastructure (Blöschl et al. 2011). Harou et al. (2010) explore the economic effects and potential adaptation strategies of water trading of California's water supply system using past droughts from paleorecords rather than climate projections. Similarly, Watts et al. (2012) test the resilience of drought plans in England to droughts that are outside recent experience using nineteenth century drought records. The method combines system modeling with an interactive approach that asks water system managers to work through the actions that they would take at different stages of the drought, without knowledge of subsequent drought development.

In the top-down approach, the hydrological modeling is usually performed in a mechanistic way by running hydrological models with prescribed boundary conditions (e.g., climate or land use scenarios), whereas the bottom-up approach has a more creative role for hydrologists to play. Their role is explorative modeling across a wide range of assumptions, contingencies, and uncertainties taking into account the expertise of local risk managers and stakeholders. The aim is to assist them in understanding the potential consequences of alternative policy options.

5.01.5 Accounting for Black Swan Events

The previous two sections discussed two alternative approaches to prioritizing hydrological risk management. There is another

Figure 5 A black swan among numerous white swans is unexpected but may be the important one. There is a potential for Black Swan events in hydrology that are unexpected but have high impact from a societal point of view. [Available online at http://www.lonelyplanet.com/japan/hokkaido/images/black-swan-among-white-swans-hokkaido$24256-1.]

facet to it. Taleb (2007) observes that the worst disasters in history have been the unexpected ones because of the inability to brace against them. He terms such unexpected large-impact events 'Black Swan events,' based on the anecdote that, before the discovery of Australia, all swans were considered to be white because of the lack of black swan sightings in the Western world (**Figure 5**). For such Black Swan events, prior risk calculations are, invariably, grossly in error. An example is the 2001 terrorist attack on the World Trade Center (Sarewitz et al. 2003). Black Swan events are unexpected and have large impacts and, interestingly, failed predictions can always be explained *in retrospective*.

Experience with unexpected events with large consequences abounds in hydrological risk management – that is to say after the fact. The Tirlyan disaster is a case in question, and there are many more. They make up the 'lessons learned' from any recent disaster. For example, the lessons learned from the 2002 flood in Austria include the following situations to be considered: blockage of reservoir spillways by an excessive amount of woody debris due to landslides into the reservoir, leaky oil tanks in the cellars of houses due to buoyancy when being flooded, and the resulting oil spills, missing local details in flood management plans such as passageways under railway embankments causing major unexpected flooding beyond the embankment. All these events were unexpected, were created by context and contingencies, and had large (potential) consequences, but they could have been easily avoided if only one had known of them *a priori*.

Unexpected large events are produced by the nonlinearities of the system (Blöschl and Zehe 2005; Koutsoyiannis et al. 2009), in particular in the interplay of the biophysical and the social system (Sarewitz et al. 2003; Sivapalan et al. 2012). Climate variability has therefore the potential to produce Black Swan events for hydrology that are unexpected but have high impact from a societal point of view.

The implications for hydrological risk management are important. The bottom-up approach has more potential to prepare for unexpected events than the top-down approach as the focus is on reducing the vulnerability of the system by robust methods. As Taleb (2007) noted *"it is much easier to deal with the Black Swan problem if we focus on robustness to errors rather than improving predictions"* (Taleb 2007, p. xxiv). For a flood management system, for example, the vulnerability of the system can be reduced by using free overflow spillways rather than funnel-like morning glory spillways since the former are more robust against hydraulic overload, by designing spillways for dikes (which is not usually done), and by planning for redundancy in emergency plans. For a drought management system, the vulnerability of the system can be reduced by increasing the connectivity of water supply infrastructure and converting permanent abstraction licenses to time-limited status, among other low-regret strategies (Wilby and Dessai 2010). They may not be optimum in an economic sense but may be more robust than alternative approaches to extreme events with large consequences. The bottom-up approach starting with the policy options at the local scale may also be more creative by exploring a wide range of possibilities causing flood- and drought-related disasters. The actual measures taken may be quite different from those resulting from the top-down approach, as in the bottom-up approach one may rank the measures by the harm they may cause rather than by their contributions to total economic risk.

The flood risk management study of Wardekker et al. (2010) is interesting in that it explores imaginable surprises, something they term 'wildcards.' The study proposes an uncertainty-robust adaptation strategy of strengthening the resilience of the city of Rotterdam, using literature study, interviews, and a workshop. The 'wildcards' or imaginable surprises for the area include thermohaline circulation collapse, port freezing events, port malaria incidents, modified German water safety policy, enduring heat and drought, extreme storm, and failure of the storm surge barrier during an extreme storm. Their resilience approach is designed to make the system less prone to disturbances, enable quick and flexible responses, and make it better capable of dealing with surprises than traditional predictive approaches.

5.01.6 Conclusions

The two main approaches to hydrological risk management are the top-down approach that starts from the projected scenarios and the bottom-up approach that starts from the vulnerability of the communities in question. While the top-down approach is conceptually appealing as it mimics the main process cascade and strives for economic optimality, the probabilities used in this approach may be difficult to estimate, in particular in a changing world. The bottom-up approach is ‘messier’ involving methods that can be less clearly structured, but it has a social motivation and is more amenable to accounting for surprises as it strives for reduced vulnerability and increased resilience by robust methods. In the bottom-up approach, risk involves possibilities rather than probabilities. The bottom-up approach has an important and creative role for hydrologists to engage in explorative modeling to assist local risk managers and stakeholders in defining policy options.

Van Pelt and Swart (2011) noted that too much focus on climate scenarios alone may lead to ineffective risk management. Montanari et al. (2010) conclude “*Offering insightful explanations for predicted changes may be more helpful than perfecting the estimates of what are inherently uncertain changes. Such a nuanced assessment will gain wider acceptance in society and will bring more credibility to the research community*.” We argue in this paper that the possibilistic thinking of the bottom-up approach (including worst cases) should not complement the scenario-based top-down approach. It is like the tail wagging the dog. It should be the converse: the bottom-up approach should be the starting point in hydrological risk management, which may be complemented by climate scenarios and economic optimality analyses. In highly vulnerable settings as they occur in developing countries, it is particularly important to perform bottom-up risk analyses, that is, to start from policy options and their risks, rather than to perform top-down modeling. Climate variability has the potential to produce Black Swan events for hydrology that are unexpected but have high impact from a societal point of view. Reducing the vulnerability and increasing the resilience of the system by a bottom-up approach leading to robust and flexible strategies will therefore be the hallmark of hydrological risk management in a changing world.

5.02.1 Introduction

Water is widely recognized as a critical Earth resource that is essential for human prosperity and healthy ecosystems. Although over 70% of our planet is covered by water, only a small fraction is freshwater that is ready for human consumption (Falkenmark 1998; Falkenmark and Biswas 1995; Gleick 2003). Furthermore, freshwater resources vary widely both in space and time that is often in conflict with water demand. The staggering numbers of people lacking access to safe drinking water (1.1 billion) and proper sanitation (2.4 billion) are well documented (http://www.who.int/water_sanitation_health/hygiene/en), resulting in a loss of 2 million people per year (mostly children under the age of 5) due to diarrheal diseases (The 2 million lives lost each year because of water-borne diseases as a fraction of the global population (0.028%) is comparable to the impact of the 2003 heat wave in Europe causing 14 802 excess deaths [http://www.earth-policy.org/plan_b_updates/2006/update56] in France alone, with a population of 65 million (0.021%)). Less emphasized is the fact that the vast majority of people (900 million) suffering from water scarcity are extremely poor, living under the one-dollar-per-day poverty line (Rijsberman 2006), which represents an inequity gap between the top and the bottom of the population similar in magnitude as the difference between the top third and the wealthiest 1%.

The world population experiencing water scarcity is expected to increase both in absolute and relative numbers and possibly reach two-thirds of the total population in the next several decades (Shiklomanov 1990; Vörösmarty et al. 2000; Alcamo et al. 2000), dominantly due to population growth. Changing climate (in terms of shifts in the norms, e.g., average temperature or precipitation) will likely play a minor role (Fekete et al. 2010; Vörösmarty et al. 2000). While growing population always exacerbates water shortages, changes in average climatic conditions would have both beneficial and detrimental impacts. Anticipated changes in the tails will increase vulnerabilities to extreme events.

A recent study (Vörösmarty et al. 2010) assessing major threats to water resources from water security and ecosystems perspectives found that rich nations in general are better equipped to mitigate water scarcity and were able in the past to secure freshwater resources to meet their needs by investment in water infrastructure. Technically, any increasing demand for resources other than energy can be satisfied by investing more energy (Gever et al. 1986) either by exploring less readily available resources or replacing with substitutes. Water is not any different in this respect, and on a planet that is covered mostly by water, there are a variety of options to satisfy water demand either by recycling consumed water, transport water from long distances, or desalinate sea waters. From long-term sustainability perspective, the need to deploy energy-intensive technologies to secure water resources is alarming since energy sources (both renewable and nonrenewable) are clearly finite and represent a strict limit to how much energy can be employed to deliver water.

The same study (Vörösmarty et al. 2010) found that threats to ecosystems are poorly addressed in the developed world and developing countries with large remaining pristine river basins still have more healthy ecosystems than rich nations with significant engineering resources. The ultimate challenge of sustainable human development is to satisfy human needs and maintain healthy ecosystems in a changing climate that could reshape significantly the available water resources.

This chapter provides an overview of the current understanding of the spatial and temporal distribution of water resources contrasted with different water uses that are typically characterized as consumptive or nonconsumptive depending on whether the utilized water is released to the atmosphere or remains in liquid form and ultimately is returned to surface or subsurface water storage pools.

5.02.2 Water Availability

Global water resource assessments have a long history dating back to the 1950s when Thornthwaite and Mather (1955) established the first estimates of key components of the continental water budget based on monthly average surface air temperature and precipitation records from over 14 000 meteorological stations worldwide (Legates and Mather 1992). Table 1 shows several estimates of global discharge fluxes to ocean from different authors since the mid-1970s.

While these estimates appear to show a wide spread (Schlosser and Houser 2007), the realistic estimates are reasonably narrow. With the exception of Korzoun et al. (1978), Oki et al. (1999), Grabs et al. (1996), Syed et al. (2010), and Haddeland et al. (2011), estimates fall within the 36 000–40 000 $km^3 yr^{-1}$ bounds that Fekete et al. (2002) argued as the plausible range based on the river discharge from available data archives.

Grabs et al. (1996) and Fekete et al. (2002) practically used the same set of discharge gauges (capturing 20 700 $km^3 yr^{-1}$ annual discharge) while monitoring ~50% of the continental land mass, which is ~70% of its actively contributing portion (Fekete et al. 2002). The difference between the two estimates arose from the assumptions about the ungauged land mass. Grabs et al. (1996) recognized that the monitored portion is about half of the total land mass and assumed that the runoff generated in the nonmonitored regions was equal to the monitored regions. Fekete et al. (2002) applied a water-balance approach to assess the discharge from nonmonitored lands and found that while 60% of the nonmonitored areas are actually too dry to maintain organized river systems and deliver significant amount of waters to oceans, the other 40% of the nonmonitored lands are actually more than twice as wet as the discharge monitored regions.

Estimates of Oki et al. (1995) and Syed et al. (2010) were both derived from the atmospheric budget based on the National Centers for Environmental Prediction (NCEP) reanalysis (Kalnay et al. 1996; Kistler et al. 2001), and the significant deviation from other estimates based on precipitation and discharge observations combined with terrestrial evapotranspiration estimates reflects more a deficiency in the NCEP reanalysis products than the uncertainties in global runoff estimates. The Syed et al. (2010) estimates also incorporated mass changes observed by the Gravity Recovery And Climate Experiment (GRACE) gravity-monitoring mission, but since the water storage change at annual time scales is normally considered negligible, this estimate is still primarily constrained by the inaccuracy of the NCEP reanalysis.

Table 1 Global river discharge to ocean estimates in cubic kilometers per year

Source	*Discharge*
Baumgartner and Reichel (1975)	37 713
Korzoun et al. (1978)	46 900
L'vovich et al. (1990)	39 700
Oki et al. (1995)	22 311
Postel et al. (1996)	40 700
Grabs et al. (1996)	42 700
Nijssen et al. (2001)	36 103
Fekete et al. (2002)	38 320
Dai et al. (2009)	37 288
Schlosser and Houser (2007)	36 000
Syed et al. (2010)	32 851
Wisser et al. (2010a)	37 405
Haddeland et al. (2011)	42 000–66 000

The NCEP reanalysis product is the result of applying the National Center for Atmospheric Research (NCAR)–NCEP operational weather forecast model in a data assimilation scheme, where the model predictions are constantly adjusted based on observed states of the atmosphere from various sensors (weather stations, balloons, and satellite data). The deficiency of the NCEP reanalysis is alarming since it reflects a general weakness in atmospheric models to realistically represent key components of the water budget. The poor representations of precipitation in global circulation models and their operational weather forecast siblings are well known (Ines and Hansen 2006; Sperna Weiland et al. 2010).

The most recent estimates by Haddeland et al. (2011) are disturbing for numerous reasons. This study was carried out as an international exercise by a number of research groups actively developing and using global land-surface (LSM) and hydrological (GHM) models. The 11 participating models were tested using the same meteorological forcing from the European Center for Weather Forecast ERA-40 reanalysis (Uppala et al. 2005) for the 1985–99 period. The reanalysis data were bias corrected based on Climatic Research Unit (CRU) air temperature, diurnal temperature range and wet days (New et al. 1999; Mitchell and Jones 2005), and precipitation from the Global Precipitation Climatology Centre's (GPCC) version 4 *full* product (http://gpcc.dwd.de).

The high discharge to ocean estimate can partly be explained by the high precipitation input that averaged 872 $mm yr^{-1}$ over the 1985–99 period. It is unclear how the ERA-40 reanalysis bias correction was carried out, but according to our own calculation the average precipitation over land from the GPCC v4 *full* gridded precipitation product is 819 $mm yr^{-1}$ so the forcing data were ~6% higher, which could lead to 10–12% more runoff alone. However, the elevated precipitation does not explain the 66 000 $km^3 yr^{-1}$ estimate, which is 60–70% higher than the plausible range between 36 000 and 40 000 $km^3 yr^{-1}$ based on gauged basins (Fekete et al. 2002).

It is hard to accept that hundreds of discharge gauges globally would have systematic low bias, but it is also infeasible that the ungauged regions (less than 30% of the actively contributing land mass) could produce three times or more discharge to the oceans than the monitored 70%. Besides the large bias in these model simulations the huge spread between models is also concerning. Prior to this study, global water resource assessments seemed to converge to the plausible 36 000–40 000 $km^3 yr^{-1}$ range, but this study shows enormous differences. If this level of model uncertainties in the modeling of the hydrological system alone is real, one has to wonder, if any of these models could be used to make realistic water resource assessments at global scale.

5.02.2.1 Contemporary Water Resources Variability

A number of studies have attempted to estimate the key components of the hydrological water budget, but less research has been done to assess its variability. A major roadblock in the accurate assessment of the time varying water budget is the lack of high-quality river discharge data that are the most accurately measured components of the hydrological cycle (Hagemann and Dümenil 1998; Grabs et al. 1996; Gutowski et al. 1997).

Probably, the most comprehensive analysis of available discharge records was carried out by Dai et al. (2009). They assembled publicly available discharge records from all over the world and performed a series of analysis to fill in data gaps (correlating discharge from nearby gauges, going back to available stage height records, relating basin-wide precipitation to discharge records). The remaining data gaps for the 1948–2004 period were filled in by linear regression between runoff estimates from the community land-surface model (CLM3) and observed discharge records. The resulting data set consisting 925 ocean reaching watersheds that covers 80% of the nondeserted, nonice and non-internal-draining areas capturing over 73% of the continental discharge into oceans is undoubtedly the most complete set of discharge records available today.

Dai et al. (2009) found that given the high interannual variations in runoff, detecting significant trends over periods of longer times are difficult. Nevertheless they found significant decreasing discharge trends in the Indian ($-5.4\ \mathrm{km}^3\,\mathrm{yr}^{-1}$) and Pacific ($-10.1\ \mathrm{km}^3\,\mathrm{yr}^{-1}$) oceans and an increasing discharge in the Arctic ($8.2\ \mathrm{km}^3\,\mathrm{yr}^{-1}$) that was consistent with previous studies (Peterson et al. 2002). They also found that in most river basins the land-surface model (CLM3) captures well the long-term runoff variations without representing irrigational water uptakes, which indicates that the impact of consumptive water use on the water budgets at large scales is still small (Milliman et al. 2008; Wisser et al. 2008, 2010a).

Wisser et al. (2010a) reconstructed the twentieth century hydrography solely by water balance estimates driven by precipitation and air temperature from the CRU of East Anglia (Mitchell and Jones 2005). They found that over the period of 1901–2002 (that the CRU data set represents) the annual runoff increased slightly by $11\ \mathrm{km}^3\,\mathrm{yr}^{-1}$, which is the equivalent of $0.03\%\ \mathrm{yr}^{-1}$ in normalized terms (with respect to the long-term average over the same period). Applying the *full* precipitation product from the GPCC (http://gpcc.dwd.de), Offenbach, Germany, in the same model from Wisser et al. (2010a) resulted in a declining trend with similar magnitude (Figure 1). Furthermore, a closer look at the time series of annual runoff during the 1901–2002 period reveals a slow increase ($17\ \mathrm{km}^3\,\mathrm{yr}^{-1}$) during the 1901–60 period followed by a more rapid decline ($52\ \mathrm{km}^3\,\mathrm{yr}^{-1}$) during the rest of the century. These separate trends are also present in the Wisser et al. (2010a) analysis. Similar trends in precipitation are characteristic features of both the CRU and the GPCC products with different magnitudes.

The trends based on GPCC precipitation in the normalized runoff (using the 1901–2002 mean runoff as a reference) by receiving oceans (Figure 2) largely agree with Wisser et al. (2010a), but a closer look reveals clear changes in the prevailing trends over time. Trends during the second half of the century have some irregularities, deviating from Dai et al. (2009). The most significant is the declining runoff in the Arctic, which contradicts a number of studies (Peterson et al. 2002; Dai et al. 2009). The rapid increase in the first half of the century is also suspect since river discharge records from Eurasian rivers suggest that the runoff was stable before 1950 and the discharge increase accelerated only after 1980 (see Chapter 5.26, Changing Discharge Patterns of High-Latitude Rivers). Rawlins et al. 2009 already recognized these inconsistencies and attributed the erroneous precipitation trends to changes in the monitoring network.

While identifying trends from both the discharge records and the water balance calculations appears to be difficult (Dai et al. 2009; Milliman et al. 2008), the water balance calculations are important tools to assess the interannual variability of the continental runoff (Table 2). Globally the continental runoff could vary between 88 and 110% around the long-term mean discharge ($37\,786\ \mathrm{km}^3\,\mathrm{yr}^{-1}$ in the GPCC precipitation simulation) in response to 95–105% variation in global precipitation ($789\ \mathrm{mm\,yr}^{-1}$). According to water balance calculations, Australia (including New Zealand and several surrounding islands) experiences the widest range (65–209%), where the extreme high runoff occurred in 1974 when the annual runoff

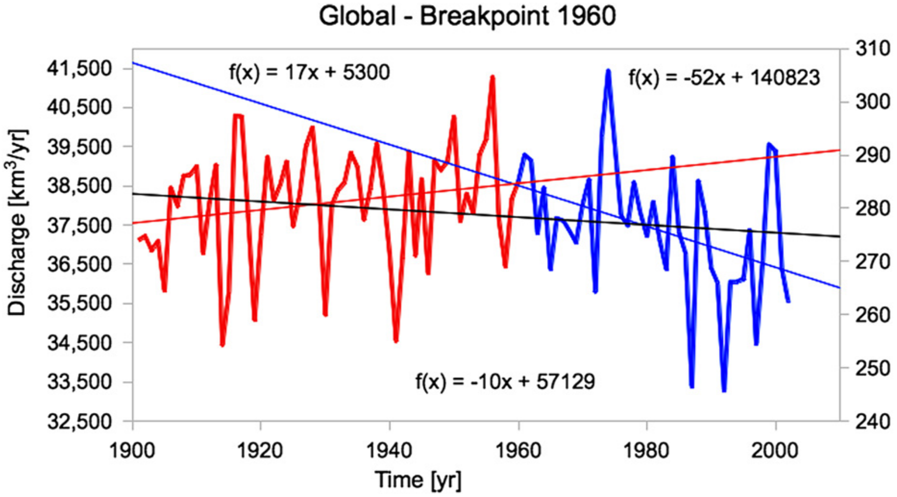

Figure 1 Twentieth century global runoff trends. The global runoff shows a $10\ \mathrm{km}^3\,\mathrm{yr}^{-1}$ decline over the 1901–2002 (thin black line), which is the result of a $17\ \mathrm{km}^3\,\mathrm{yr}^{-1}$ increase from 1901–60 (thin red line) followed by a rapid $52\ \mathrm{km}^3\,\mathrm{yr}^{-1}$ decline (thin blue line) after 1960.

was more than twice (2386 $km^3 yr^{-1}$) the long-term average (1144 $km^3 yr^{-1}$) in response to 922 $mm yr^{-1}$ annual precipitation, which was 41% above normal (652 $mm yr^{-1}$). This degree of runoff response magnification to increased precipitation might be partially due to deficiencies in the water balance formulation, but the tendency of disproportional increase in runoff due to increased precipitation is still a characteristic of the runoff generation processes (Fekete et al. 2004). In general, the water balance model runoff response is consistent with the reported runoff elasticity in the literature (1% change in precipitation causing 2–3% change in runoff) (Chiew et al. 2006; Fu et al. 2007; Sankarasubramanian et al. 2001).

5.02.2.2 Future Water Resources

Water resources under future climatic conditions are major concerns in terms of climate vulnerability. A number of studies attempted to assess changes in water resources under future demographic and climatic conditions (Alcamo 2005; Arnell 1999; Arnell and Liu 2001; Fekete et al. 2010; Vörösmarty et al. 2000). The inherent uncertainty in these studies comes from the inevitable reliance on global circulation models that have limited skills in even reproducing present day climate (Stephens et al. 2010).

Climate models predict more precipitation globally under future climatic conditions, which, in the models, is more pronounced over oceans than over land (Arnell 1999), but show some agreements regionally (more precipitation in the tropics and at high latitude and a decline in precipitation in the Sahel region) (Allen and Ingram 2002). The competition between elevated evapotranspiration due to higher air temperature and increasing precipitation would dictate whether particular regions experience an increase or a decrease in water resources. It is important to recognize, of course, that the climate model regional predictions of changes in weather and other climate statistics have not been shown to be skillful in hindcast predictions with these models (Pielke and Wilby 2012).

Table 2 Continental discharge/runoff variations[a]

Region	Discharge ($km^3 yr^{-1}$)	Runoff ($mm yr^{-1}$)	Normalized minimum (%)	Normalized maximum (%)
Africa	5557	185	72	125
Asia	11 932	268	80	120
Australia	1144	139	65	209
Europe	2041	201	69	136
North America	5693	232	84	120
South America	11 419	636	80	113
Global	37 786	278	88	110

[a] *Annual discharge from continents along with average annual runoff is given in the first two columns along with normalized range of discharge/runoff fluxes referenced to the 1901–2002 long-term average.*

A recent study by Fekete et al. (2010) carried out water balance estimates based on Millennium Ecosystem Assessment climate scenarios. Climate scenarios under present and future conditions (centered around 2030 and 2050 referred as +30 and +50 year sensitivity experiments) were generated by the Integrated Model to Assess the Global Environment (IMAGE v2.4) (Bouwman et al. 2006). The future scenarios followed the Millennium Ecosystem Assessment (MEA) story lines (Alcamo 2005): Adapting Mosaic (AM), Global Orchestration (GO), Order from Strength (OS), and Technogarden (TG) representing different human development strategies with respect to socioeconomic trends (globalization or regionalization) and environmental management (proactive or reactive). Climate forcings (air temperature and precipitation) from the IMAGE model were used in a revised version (Wisser et al. 2010a,b, 2008) of the Water Balance/Transport Model (WBM/WTM) by (Vörösmarty et al. 1989, 1998) incorporating key human alterations (irrigation and reservoir operations) to the water cycle to assess changes in hydrography.

The results of this study are summarized in Figure 3. The first two rows (Figure 3(a)–3(f)) show the latitudinal anomaly characteristics of air temperature and precipitation under present and future conditions. Temperature anomalies for the twentieth century (Figure 3(a)) based on hundred-year gridded data from the CRU (Mitchell and Jones 2005; New et al. 1999) (maximum and minimum averaged by latitude shown in solid line) envelop almost entirely the elevated temperature in the +30 years experiment (Figure 3(b)). The projected temperatures step out from the twentieth century climate variability under most of the Millennium Ecosystem Assessment (MEA) scenarios only by +50 years experiment (Figure 3(c)).

In contrast, the precipitation (which goes both up and down by latitude with respect to the twentieth century climatology (Figure 3(d)) unlike air temperature that only goes up at all latitudes) stays well within the standard deviations (shown as dotted line) of contemporary precipitation. The different development strategies have marginal effects on future precipitation (Figure 3(e) and 3(f)), while significantly different deviations from contemporary air temperature emerge according to the +50 years experiment (Figure 3(c)).

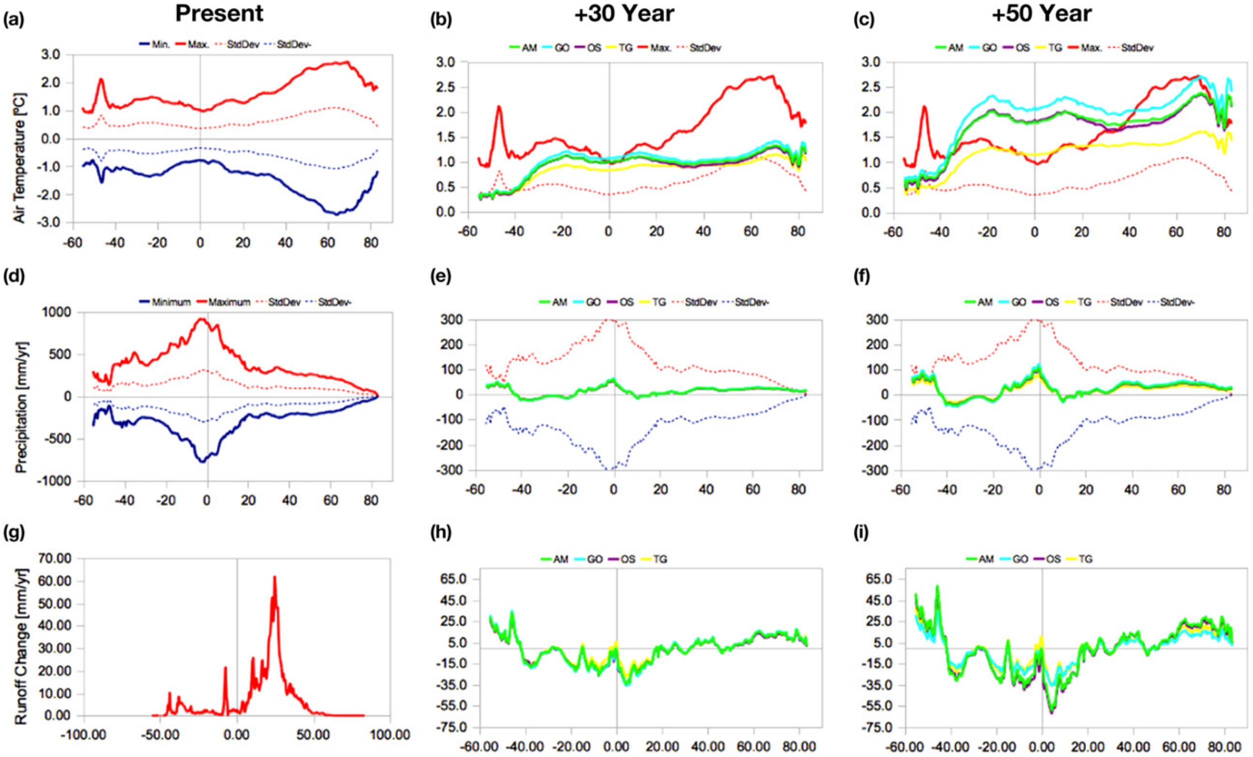

Figure 3 Millennium Ecosystems Assessment Scenarios. The top two panels show the latitudinal deviations of annual air temperature and precipitation averaged by latitude from the long-term mean according to the CRU time series. The second and third rows show the air temperature and precipitation change (respectively) by latitudes for +30 and +50 year sensitivity experiments relative to contemporary (year 2000) climate. Reproduced from Fekete, B. M., D. Wisser, C. Kroeze, E. Mayorga, L. Bouwman, W. M. Wollheim, and C. J. Vörösmarty, 2010: Millennium ecosystem assessment scenario drivers (1970–2050): climate and hydrological alterations. *Glob. Biogeochem. Cycles*, **24**.

The runoff response to changing climates (Figure 3(h) and 3(i)) differs as a function of latitude. At low latitudes, the increased evapotranspiration as a result of the elevated temperature dominates, which offsets the increased precipitation, resulting in a reduction of runoff in the water budget. At higher latitudes that precipitation increase plays the dominant role yielding more runoff.

Figure 3(g) shows the difference in runoff by latitude under present day climatic conditions turning the human alterations on and off, indicating that the impact of contemporary consumptive water uses is already in par with possible changes in the hydrological cycle due to climate. This study confirms the results of studies by both Arnell (1999) and Vörösmarty et al. (2000) that changes in the norms of key climatic variables such as air temperature and precipitation will have both negative and positive impacts on water resources, while direct impacts of water use on water availability would be exclusively negative.

None of these studies were able to address the adverse impact of the anticipated increase in extreme events. Current-generation climate models are not really suited for such studies since they are often limited to coarse time (monthly) and spatial scales (25–300 km) (Wilby 2010). They also lack the ability to replicate subgrid scale processes, complex topography, known lapse rates, and local snow–ice feedbacks (Wilby 2010), which are all critical in capturing high-frequency signals.

5.02.3 Water Use

Global estimates of water use agree that the dominant utilization is irrigation (Rosegrant et al. 2002; Döll 2002), but the actual proportion has significant uncertainties between 70 and 90% of the total water use. While irrigational water use is primarily consumptive and affects the quantity of water resources, other water uses (domestic, industrial, or agricultural) are typically nonconsumptive, impacting water quality.

5.02.3.1 Consumptive Use

Consumptive water use is estimated to range between 1200 and 1800 $\mathrm{km^3\,yr^{-1}}$ (Döll 2002; Vörösmarty et al. 2005), which is about one-third of the 6800 $\mathrm{km^3\,yr^{-1}}$ freshwater used for food production (both irrigated and rain fed) (Rockström et al. 2007). Additional 2200 $\mathrm{km^3\,yr^{-1}}$ freshwater will be needed to alleviate hunger in the next decade to accomplish the United Nations' Millennium Development Goals. This increase in freshwater appropriation can be met partially by an additional 270 $\mathrm{km^3\,yr^{-1}}$ irrigation (Rockström et al. 2007). The actual irrigational water withdrawal is higher (2500–3200 $\mathrm{km^3\,yr^{-1}}$) (Hanasaki et al. 2008; Döll 2002; Wisser et al. 2010b) than the estimated consumptive water use (1200–1800 $\mathrm{km^3\,yr^{-1}}$), but a significant portion of the irrigated water returns to surface and subsurface water bodies.

Agricultural water use traditionally was equated with irrigational water uptake, but more recently researchers started to argue that from food production perspectives all the waters that the crops utilize should be accounted for (Rockström et al. 2007; Rost et al. 2008). Irrigational water use is often regarded as blue water and rain-fed agricultural water use is termed green water. Green water use does not necessary affect the overall water budget of a region in a sense that conversion from natural ecosystems to cropping plants may actually decrease evapotranspirational water losses and increase runoff particularly when forested lands are replaced (Coe et al. 2011; Findell et al. 2006).

Accounting for green water is more important when crop trading is considered, which can be viewed as a form of water trading. Crops produced in water-rich areas are viewed as virtual water transfers that can alleviate pressure on water resources in water-deprived regions.

5.02.3.1.1 Blue Water

Consumptive agricultural water use is still a small fraction of the continental runoff (Döll 2002; Rockström et al. 2007), but occurs in water scarce areas, where irrigational water use often competes with other sectors (municipal and industrial) and ecosystems. Only one-fifth of the agricultural lands are irrigated, yet they provide 30–40% of the global food production (Döll 2002; Rost et al. 2008). This higher contribution is partly due to intensified agriculture, which relies more heavily on fertilizers, pesticides, and high-yield crop varieties, referred to as 'green revolution,' but partly due to eliminating the potential of crop failures in drought conditions.

Irrigated agriculture is clearly an important means to mitigate climate vulnerability at the price of significant investment in the necessary engineering infrastructures and severe alteration of the hydrological system. Perhaps one of the most extreme examples of intensive engineering is the Colorado river systems, which provide water to five states within the Colorado basin, largely for irrigation and partially for municipal water use (Figure 4) besides one-third of its water being transferred to neighboring river basins.

Besides interbasin transfers, irrigational water demand is often satisfied from groundwater sources. In the United States, 65% of the irrigated water is drawn from groundwater (Pimentel et al. 2004), and similar ~50% groundwater abstractions for irrigation are reported in India (Singh and Singh 2002). A significant portion of these water abstractions is withdrawn unsustainably from deep aquifers, resulting in steady drops in groundwater levels (Wada et al. 2010; Konikow 2011).

Several authors attempted to estimate the rate of unsustainable water extractions from deep aquifers, but these estimates show a wide spread. Vörösmarty et al. (2005) suggested that 16–33% (400–800 $\mathrm{km^3\,yr^{-1}}$) of the agricultural water withdrawal is extracted unsustainably. Rost et al. (2008) estimated the consumptive water use assuming no limit on irrigation (IPOT 2534–2566 $\mathrm{km^3\,yr^{-1}}$) versus under resource limitations (ILIM, 1161–1249 $\mathrm{km^3\,yr^{-1}}$), when irrigation is constrained to the available renewable water resources and suggested that the difference between the two estimates (1400 $\mathrm{km^3\,yr^{-1}}$) would need to come from nonrenewable or nonlocal supplies via interbasin transfers. They suggested that the difference between this estimate and that from Vörösmarty et al. (2005) primarily stems from the differences in their search algorithm to identify renewable water resources before assuming that the irrigational water demand was satisfied from nonrenewable sources. Rost et al. (2008) also estimated that only 730 $\mathrm{km^3\,yr^{-1}}$ is consumed (of the 1400 $\mathrm{km^3\,yr^{-1}}$ abstraction) and the rest actually returns to surface waters. Wada et al. (2010) using a similar global hydrological model

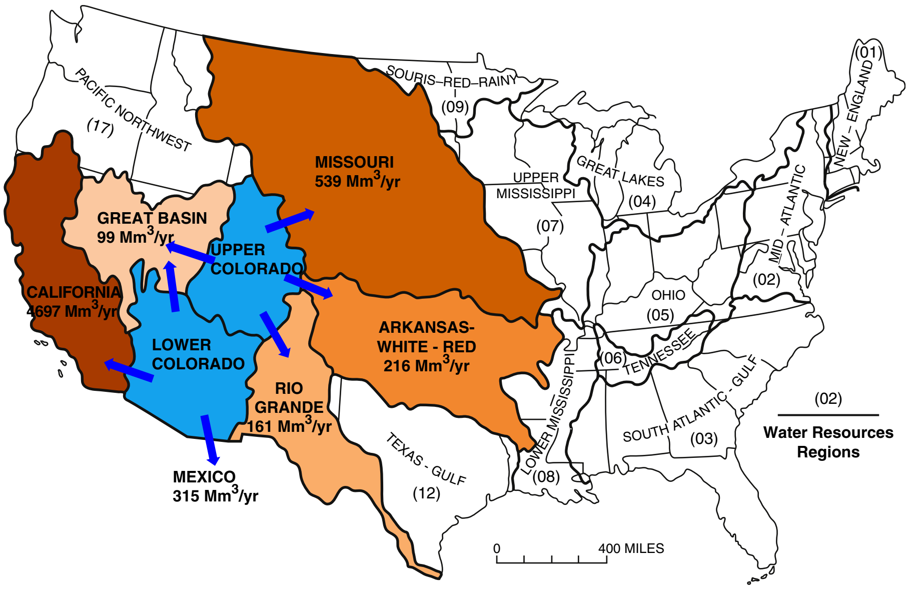

Figure 4 Interbasin transfers from the Colorado.

calculated 734 ($\pm$83) km^3 yr^{-1} groundwater abstraction for year 2000, of which 283 ($\pm$40) km^3 yr^{-1} came from unsustainable sources. Wisser et al. (2010a) arrived at 1200 km^3 yr^{-1} estimates of unsustainable water abstraction under contemporary conditions that rose from 220 km^3 yr^{-1} since the beginning of the twentieth century and concluded that over 55 000 km^3 water was withdrawn in the past 100 years.

Konikow (2011) recently questioned the high estimates and argued that previous assessments based on flux-based water budget calculations are inadequate in representing the true replenishment of groundwater aquifers and therefore they tend to overstate the magnitudes of unsustainable groundwater extractions. He carried out volumetric estimates from a variety of sources, including groundwater level measurements, pump age data, gravity change measurements from GRACE (Rodell et al. 2009; Famiglietti et al. 2011), and deterministic groundwater models, and found that groundwater depletion was significantly lower (145 km^3 yr^{-1}) averaged over the 2000–2008 period. He also estimated that the cumulative withdrawal since 1900 to 2008 was 4500 km^3, which could be responsible for more than 6% (12.6 mm) sea level rise during the same period.

Prorating the 55 000 km^3 groundwater depletion estimate from Wisser et al. (2010a) (which was consistent with Vörösmarty et al. (2005)) would suggest that over 73% of the sea level rise was due to unsustainable water withdrawals, which appears to be unrealistic. While the actual groundwater depletion is likely to be less than simple, flux calculations suggest that some of the differences between the volumetric and the flux estimates are likely to represent a major rearrangement where the water is stored since return flows from irrigated lands do not necessarily recharge the originating aquifers.

Slow recharging groundwater aquifers are undoubtedly unsustainable water sources for long-term operation of irrigation systems. The alternatives are operating reservoir, interbasin transfer, or desalination of seawater in coastal areas.

Reservoirs can capture excess water originated from the headwaters and control the timing of water availability. Over 45 000 large reservoirs (defined as higher than 15 m and exceeding 3 million m^3 volume) are in operation globally (Moore and Dore 2010) with 7000–8000 km^3 cumulative storage capacity (Vörösmarty et al. 1997; Lehner et al. 2011). About half of the world's large dams were built primarily to support irrigation (Richter et al. 2010) that directly contributes to 12–16% of the world's food production (WCD 2000), which is roughly one-third of the food produced on irrigated lands. Despite their obvious benefits, large dams are highly controversial in terms of the societal impacts (e.g., 40–80 million people were displaced by large dams), ecosystems degradation (Pringle et al. 2000; Dudgeon et al. 2006; Freeman and Marcinek 2006), and changes in riverine sediment delivery (Milliman and Syvitski 1992; Syvitski et al. 2005), with far reaching impacts on coastal areas. Large irrigation projects particularly in sub-Saharan Africa are often found costly and environmentally unsustainable (Ngigi 2003).

Interbasin transfers are highly intrusive alterations of the hydrological cycle with serious impact on aquatic ecosystems (Davies et al. 1992). While a large body of literature exist describing individual projects, no comprehensive study assessing its magnitude globally has been carried out yet. Interbasin transfers are almost epidemic, affecting river systems all over the world (e.g., Brazil (Carvalho and Magrini 2006), China (Berkoff 2003), India (Jain et al. 2005, 2008), South Africa (Swatuk 2010), and Spain (Ballestero 2004)). The Colorado river basin is probably one of the most extreme cases, where of the 18.44 km^3 yr^{-1} runoff (Blinn and Poff 1997) generated over 15% of the catchment area only 0.315 km^3 yr^{-1} crosses the Mexican border. While the majority of its water is consumed within the Colorado basin, over 31% (5.734 km^3 yr^{-1}) is transferred to neighboring basins (Figure 4).

Millions of small reservoirs, ponds, cisterns, tanks, and other microstorage facilities supplying water for very small areas (e.g., 1.5–50 ha in India (Gunnell and Krishnamurthy 2003)) are the basis for rainfall (or runoff) harvesting. Rainwater harvesting is an ancient technique (Oweis and Hachum 2006; Pandey et al. 2003), which has been a key in securing crop productions and improving yields (Wisser et al. 2010b). It is considered a compromise between green and blue water, which has less negative impact on riverine ecosystems and yet allows the utilization of local runoff. While rainwater harvesting has a rich literature, very few attempts has been made to quantify its significance globally (Wisser et al. 2010b).

A recent study by Wisser et al. (2010b) was probably the first that implemented small reservoir operation in a water balance model context (Vörösmarty et al. 1989, 1998) and concluded that these small-scale irrigations can provide 623–1122 km^3 water of their estimated 3250 $km^3 yr^{-1}$ irrigational water demand. Interestingly, their model simulations showed only a small decrease (from 49 to 44%) in unsustainable extractions, because harvesting rainwater largely prevented the recharging of the shallow groundwater that served as the secondary source of water resources before satisfying water demands from rivers and reservoirs and ultimately from unsustainable sources.

5.02.3.1.2 Green Water

Rain-fed agriculture provides the majority of the food production and will continue to do so (Rockström et al. 2007), yet their impact on water resources was neglected in the past. This negligence is not necessarily surprising, since rain-fed crops obviously replace natural vegetation, which also consumes water; therefore, green water use does not necessarily affect the overall water budget. Assuming that natural vegetation is in equilibrium with the available water, the intuitive expectation is that conversion to cultivation without irrigation is unlikely to increase evapotranspiration unless the planted crops have significantly better means to adapt to varying water availability. For instance, eucalyptus trees and other fast-growing exotic tree species could actually transpire more water than available from precipitation by reaching the groundwater with their deep roots and subsequently lowering the groundwater table (Calder et al. 1997).

Perhaps, the most important challenge in rain-fed agriculture is coping with climate variability. The crop yield improvement in the last several decades regarded as 'green revolution' was largely accomplished by reducing crop diseases through breeding more resistant crops or applying pesticides and supplying additional nutrients (Hazell 2002, 2009). For instance, the successful eradication of wheat rust, which had threatened wheat producers perennially before, via the introduction of resistant wheat varieties, resulted in the protection of 117 million hectare crop land (Chhetri and Chaudhary 2011). The introduction of inorganic fertilizers utilizing the Haber–Bosch process already has led to anthropogenic nitrogen fixation that surpassed the rate of natural processes (Rockström et al. 2009).

The introduction of more drought-resistant crops is widely viewed as the next critical step in food security (Cattivelli et al. 2008). Elevated CO_2 in the atmosphere accelerates plant growth (Daepp et al. 2000), particularly nitrogen-fixating plants, but water shortage can halt that acceleration (Aranjuelo et al. 2009). An increased CO_2 concentration is found to raise drought tolerance (Lin 2002).

Even if the introduction of drought-tolerant crops combined with the effects of CO_2 fertilization improves crop yields and reduces vulnerabilities to climate variations, regional crop failures and food shortages will remain inevitable, which can be mitigated by international food trade.

5.02.3.1.3 Virtual Water

Food trading is recognized as virtual water transfer (Ercin et al. 2009; Aldaya et al. 2010) and more recently as implied virtual land export (Fader et al. 2011). The term 'virtual water' was introduced by Allan (1993) almost two decades ago, but it took another decade to enter into global water resource assessments (Horlemann and Neubert 2002).

Obviously, not all food trading is driven by water resource limitations, and one could introduce analogous concepts of 'yellow' and 'red' radiation, reflecting the need for artificial light or heat to grow certain crops in cold climate. The 'yellow' and 'red' radiation and the corresponding 'virtual' radiation can explain the rationale of exporting high-value irrigated crops (e.g., olives, vegetables, and fruits) from dry countries (e.g., Israel) to water-rich regions (Canada or Northern Europe).

The differences in water demand to grow the same crops in different regions complicates further the virtual water accounting. For instance, growing wheat in France needs 1/10th of the water required to grow the same crop in Moroco (Mekonnen and Hoekstra 2010). Fader et al. (2011) presented a comprehensive water footprint accounting, which distinguishes green, blue, total, and external water footprint based on establishing green, blue, and total water balance and calculating green and blue water import and export. They concluded that virtual water trade is dominated by green water and food trading reduces water footprint, allowing the growing of crops where it is more efficient from water use perspective.

The promotion of international food trading contradicts the suggestions to increase local food productions often advocated by environmentalist groups, and flies against traditional desires for national self-sustainability that has led countries to go to the extremes like growing wheat in the deserts of Saudi Arabia.

Apparently, no study has been carried out yet to quantify virtual water trading as a means to increase food production's resiliency to climate variability. Just like long-distance power lines are a key for increased utilization of intermittent renewable energy sources such as wind or solar, water trade can clearly mitigate temporal water shortages due to regional crop failures. Negative examples exist, where trading agricultural products decreased resiliency in the exporting countries. Perhaps the most tragic example was the Ukraine famine in 1932–33, when millions died while the Soviet Union was still exporting grains despite poor crop production (Kuromiya 2008).

5.02.3.2 Nonconsumptive Water Use

Nonconsumptive water use, as its name implies, does not reduce water availability but typically degrades its quality. This water quality degradation is not taken into account adequately in most of the global water use estimates (Simonovic 2002).

Nonconsumptive water uses and the corresponding wastewater disposal have more severe environmental impacts than their volumetric accounting alone.

Traditionally, nonconsumptive water uses are categorized as industrial, domestic, or agricultural, although from the water resource perspective it might be more appropriate to distinguish the type of contamination regardless of its primary source. However, giving a full account of all the possible constituents far exceeds the anticipated extent of this chapter.

Solution to pollution is dilution. In other words, constituent loading to freshwater ecosystems are more harmful when they pass some critical concentration threshold. One could view wastewater disposal as a virtual water use, where certain amount of diluting 'clean' water is needed to allow the release of the wastewater. The amount of diluting water demand depends on the wastewater amount and the concentration of the constituents that the wastewater carries. Operating wastewater treatment facilities to remove some of the contamination before the wastewater is released helps to reduce the need for diluting 'clean' water, but at the cost of using energy in the water-treatment process.

A recent paper by Hoekstra and Mekonnen (2012) introduced the concept of gray water as a means to articulate water pollution in the context of unified water footprint accounting. They found that gray water is responsible for 15% of the total water footprint, which is the second largest after green water (at 74%) and higher than blue water (11%). Since green water dominantly replaces water uptake by natural ecosystems, this finding demonstrates that from the water resource management perspective water pollution from nonconsumptive use (gray water) is in the same magnitude as consumptive water use (blue water).

5.02.3.2.1 Domestic Water Use

Domestic water uses (just like energy use) are closely linked to wealth and human development. Figure 5 shows the per capita daily water use as a function of human development index (HDI). The HDI introduced by the United Nations Development Programme (UNDP 1990) combines various human development metrics (life expectancy, education, and income) as a single measure of human welfare. Similar to energy use and gross domestic product (GDP), domestic water use is closely linked to wealth and HDI. The poorest one-fifth of the population that lacks access to basic services such as electricity, clean water, and sanitation has significantly lower domestic water use than developed nations.

The cumulative curve of the population (green line) ranked by HDI in Figure 5 increases more rapidly than the cumulative curve of the domestic water use. Sudden jumps in both curves correspond to populous nations (e.g., India and China). The deviation between the cumulative population and domestic water curves reflects a serious inequity where three-quarters of the global population uses the same amount of water for domestic purposes as the remaining one-quarter. While better water management and improved water use efficiencies are keys to reduce water use in developed nations (Totten et al. 2010), developing nations with low domestic water use on the per capita basis will have nowhere else to go but to increase significantly their water use, and this increase undoubtedly will outpace any change in available water resource due to climate.

Perhaps a characteristic example where water resources are under serious stress is China, which has the same amount of water resources as Canada but 100 times the population (Wu et al. 1999). Putting it in deferent perspectives, China has 22% of the global population and 6% of the freshwater resources (Dabo and Hubacek 2007), which is distributed unevenly within the country. Half the population lives in North China, which has only 20% of the national freshwater resources (Dabo and Hubacek 2007). Rapid economic growth has led to a doubling of wastewater production in a decade from 1990 to 2000 (Wu et al. 1999). China already treats 47.5% of its wastewater, which is well above the 10% global average (Gao et al. 2008). Despite the reasonably high level of wastewater treatment for a developing country, 45% of the rivers surveyed

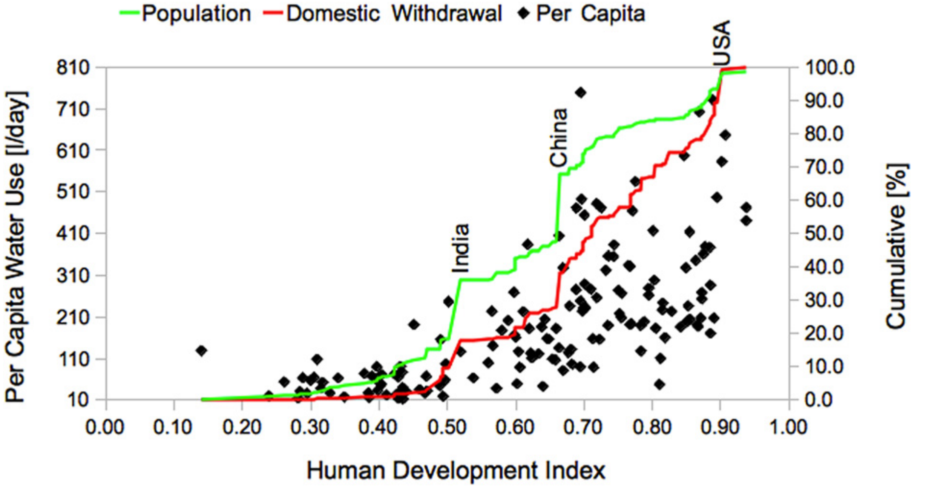

Figure 5 Domestic water use by human development index (HDI). The figure shows the relationship between per capita domestic water use (black diamonds) and HDI (left axis) contrasted by the cumulative population (green line) and per domestic water use (red line) ranked by HDI and expressed as the percent of the global total (right axis). Sudden jumps in both the cumulative curves correspond to countries with a large population.

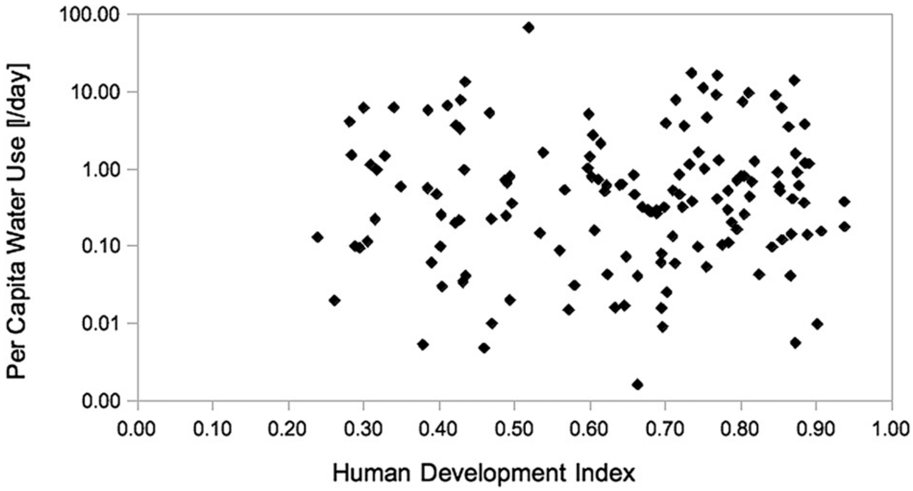

Figure 6 Industrial water use per capita as a function of human development index from Food and Agriculture Organization (FAO) Aquastat.

were polluted moderately to severely (Ministry of Environmental Protections 2009). China is going through a development path similar to that developed countries went through throughout the twentieth century, which severely impaired aquatic ecosystems before starting to invest in environment protection.

Countries need to reach a certain level of wealth before they can deal with environmental concerns following the environmental Kuznets curve (Dinda 2005), which leads to inevitable environment degradation before improvements.

Recent research by Vörösmarty et al. (2010) carried out global assessments of the various threats to riverine freshwaters, which is the dominant contributor to freshwater resources (World Water Assessment Programme 2009), and demonstrated that rich countries are able to reduce the threats to their water resources by investing in water infrastructure. These investments tend to deal with the symptoms rather than 'curing' the cause and often are inadequate to address the threats to biodiversity.

5.02.3.2.2 Industrial Water Use

Industrial water use differs from domestic water use only in the type of contaminants released in large quantities. For instance, accidental cyanide spills from goldmine operations have long-lasting effects on aquatic ecosystems (Gacsi et al. 2005; Lakatos et al. 2003; Shehong et al. 2005). Heavy metals and toxic chemicals in large quantities rarely originate from domestic sources.

Industrial water use per capita shows a wide spread among different countries and appears to be completely decoupled from human development (Figure 6). This decoupling probably reflects the tendency for poor countries to become exporters of more water-intensive raw materials and industrial products. As in the case of domestic water use, industrial wastewater either needs more diluting water when released into surface waters or needs to be treated, which is typically energy intensive.

A special case of industrial water use is water withdrawal for coolant for thermoelectric power plants (both fossil and nuclear powered). Cooling water is used both consumptively (when the water is evaporated in cooling towers) and nonconsumptively (when thermally 'polluted' water is returned to surface waters). While thermal contamination largely can be dealt with in a manner similar to chemical constituents, where the key is the availability of sufficient amount of diluting water, the challenges to secure cooling water demand will be undoubtedly exacerbated by global warming.

In the European Union, 43% of the water demand is for use as cooling water (Rübbelke and Vögele 2011), which is essential for power generation. The temperature differential between the power plants and their environment is an important factor determining power plant efficiency (Mideksa and Kallbekken 2010). A 1 °C rise in temperature could cause a small (0.45–0.8%) but not insignificant reduction in power plant efficiencies (Mideksa and Kallbekken 2010).

Heat waves that often coincide with prolonged droughts can severely compromise power generation at the time when demand for electricity is typically high. The 2009 heat wave in France caused cooling water shortages (Rübbelke and Vögele 2011), resulting in a loss of one-third of the nuclear power capacity, and France (which is normally an exporter of electricity) had to import from the United Kingdom. The 2003 heat wave led to a similar water shortage when 30 nuclear power plants had to reduce their electricity output (Rübbelke and Vögele 2011).

5.02.4 Conclusions

Water resources are under serious anthropogenic stresses already. While climate and particularly possible increase in extreme events would exacerbate the challenges to secure water for human consumption and maintain healthy ecosystems, the dominant pressure on water resources will remain as various human activities (consumptive and nonconsumptive water uses) directly affect the water cycle.

This pressure will only increase in most parts of the world where one-third of the population lives in conditions not very different from medieval Europe and another third has a living standard more close to life in the nineteenth century Europe or

North America. Improving efficiencies and better water management can reduce the anthropogenic stresses in developed countries. In contrast, the majority of the world's population has no other choice than to increase their 'footprint' in all aspects of resource utilizations (primarily their energy and water use) intensified by population growth as long as they aspire to have a comfortable life.

The lifestyle choices at the bottom one-third of the population are not whether they should take a shower twice a day or use a water-efficient shower head, but if they have to carry their cooking water on foot from long distance. The eradication of poverty, malnutrition, and illiteracy are not only a moral obligation to anybody who is concerned about inequity but also the ultimate path to stabilize population that is essential to sustainability.

According to recent projections by the United Nations (United Nations 2011), 42% of the global population already lives in countries where the fertility rate is below reproduction level and another 40% have intermediate fertility (2–3 children per woman). Only 18% lives in high-fertility countries, with more than three children. While large differences exist between countries because of cultural, ethnic, and religious circumstances, the main factors controlling the fertility rate are education and wealth (Shirahase 2000; Okazaki 1981; Shukla 1982). While the latter leads to increased life expectancy, which contributes to population growth, the lower fertility rates offset that rapidly.

The focus on climatic change apparently hijacked the attention to alleviation of hunger, providing access to clean water, and proper sanitation or improving education in the last two decades, which should have remained in the forefront in globally orchestrated actions to move human development onto a more sustainable path. The alternatives, burning food crops as transportation fuel, which drives up food prices, denying access to cheap energy to the poor as the unintended results of current policies in place to combat climate change, are not only failing but are also facing growing objections from the developing world. The path to sustainability is clearly an expedited economic growth in the developing world to shorten the rising trajectory of the environmental Kuznets curve, enabling developing countries to get on the declining environmental stress side sooner.

5.03.1 Introduction

5.03.1.1 Extremes in Precipitation

The term 'extreme' has two meanings, one of them is purely mathematical; for example, when we have a sample X(i), ($i = 1, 2, \ldots, n$) from an arbitrary distribution and the sample size is sufficiently large, the values at the distribution's upper tail more and more closely (asymptotically) follow the specific, narrow defined sets of distributions defined by the extreme value theory (cf., Coles 2001). Furthermore, the absence of precipitation (P) is quite common and under extremes at the low end of its distribution; we include prolonged intervals without P (including miniscule values) that are 'sufficiently rare.' Values at the tail of the probability distribution technically qualify to be considered as 'extremes.' However, there is no common agreement as to how far from the center of this distribution the 'extremes' lie. The definition of 'extreme' may well depend on the scientific, social, political, engineering, etc. application in order to evaluate the size of the 'extreme' we are looking for. Upper 5% of daily events, maximum annual value, etc. were frequently used in theoretical climatological assessments (e.g., IPCC 2007), but in other areas (e.g., hydrology, civil engineering, studying natural and anthropogenic hazards) the term 'extremes' has a *negative* connotation. It is more widely used to describe situations that cause damage that must be prevented, mitigated, and/or accounted for long-term planning such as construction of houses, bridges, other infrastructure, human health protection, and water management. Therefore, another definition of the extreme precipitation term is 'human-defined.' Nature knows no bad weather, but we as a society do. We consider each weather event that affects societal well-being (human health, harvest, flood, drought, water supply, property value, and infrastructure) as an extreme event. For the lower tail, the 'human-defined' sibling of the extreme term, drought, is measured by its impact on society and the environment.

While two approaches to introduction of the term 'extreme' are intertwined and coincide at the very end of the tails of precipitation distribution, different segments of the scientific community may focus on the term differently, which can cause confusion and/or misunderstanding. Some typical examples are as follows:

- A 2-inch daily rainfall event in the US Midwest might be categorized as 'extreme,' but under most circumstances a farmer would be grateful for this rainfall in the early summer.
- Classification of the upper 5% (or similar percentile) of rainy days as 'extremes' may be troublesome. For some, an 'extreme' connotes a sense of emergency, which may convey an inappropriate response.

These are legitimate concerns that warn 'pure' scientists not to juggle with the words but provide responsible answers on the topic that is of high-impact practical importance. Therefore,

http://dx.doi.org/10.1016/B978-0-12-384703-4.00501-3

early on, when climatologists begin talking about increases in the high end of precipitation distribution (both frequency and intensity), they have used more neutral terms such as heavy, very heavy, and intense rain events (cf., Groisman et al. 2001). The term 'extreme rain event' was left to the events that would undoubtedly cause damage (e.g., rainfall of 150 mm d^{-1} or above). Not everyone accepted these terms, however. Moreover, not everybody was happy when instead of a selection between two categories, 'average' and 'extreme,' more sophisticated gradations were introduced that, in addition, vary between the research teams and regionally.

5.03.1.2 Definitions of Intense Precipitation

There is no way to avoid definitions of intense, heavy, very heavy, and extreme precipitation. Throughout this chapter we shall use several of them because these definitions are regionally specific and we are reviewing the results of different authors. We combine these definitions in Table 1 and each time these vague terms are used, we will clarify which definition was used and why.

There are two major types of definitions for the upper end of precipitation distribution. They can be partitioned in two classes associated with fixed thresholds (when a precipitation event is assigned to a particular class according to its absolute value, e.g., above 100 mm day^{-1}) and percentile defined thresholds (when a precipitation event is assigned to a particular class according to the frequency of its occurrence, e.g., once in 10 years or in the upper 1%, etc.). There are pro and contra reasons for selection of both types of thresholds. By selecting fixed thresholds for heavy precipitation of various intensities within a region, we initiate a preselection of locations where the micrometeorological conditions induce these events to be more frequent. Examples are sites located on windward slopes versus leeward slopes, coastal regions versus inland sites, etc. In extreme cases (which are exactly a target of our assessment), we may unintentionally include only a few locations where extreme precipitation occurs due to a combination of orography and atmospheric circulation causes (e.g., Yakutat, Alaska; foothills of the Himalaya Mountains). These results, when regionally averaged, do not represent the entire region but only its most humid areas. But, why is it worthwhile to look for extremes in the places where they do not (or are less likely to) occur? Using the percentile thresholds that are crafted individually for each location, we (with additional help of a carefully selected area-averaging procedure) receive a much better spatial representativeness for each region that accounts equally for precipitation extremes, for example, west and eastward of the Cascade Range in the Washington State. The last example clearly identifies one of the problems of the percentile approach: *it levels quantitatively disastrous and moderate precipitation events* that may negatively impact hydrological estimates of consequences of intense rainfall over the rough terrain (even while the places that are used to huge precipitation events may have an infrastructure that is designed to take it). The second problem with the percentile approach, when we are looking for 'real' extremes, is low accuracy of individual threshold estimates at the far end of the tail of the empirical distribution. At the right-side tail, the ranked time series provides a broad range of neighboring values that may differ from each other by scores of millimeters. Thus, the estimated 'threshold' carries with it both a peculiarity of the individual observing period at the site and a large random error of the estimate.

The discussion above suggests that by bypassing the percentile estimates, one can be better off by avoiding these two hidden caveats (leveling and low accuracy of the variables that are used only at an intermediate step of assessment). In the past, we experimented with and used both types of precipitation thresholds. In our opinion, the upper 5% of daily precipitation events (that across the conterminous United States on average occur 20 times per year and bring about 30% of annual precipitation totals) and/or a mean peak annual precipitation event do not qualify for the definition of 'extremes.' That is why 10 years ago we began using more neutral terminology 'heavy,' 'very heavy,' and 'intense' precipitation (cf., Groisman et al. 2001, 2005). The current concern is the possible changes in 'real' extremes, i.e., those that do endanger human life and/or well-being. These extremes are associated with very rare precipitation events.

We also have to admit that the ongoing (and projected) changes in precipitation do not fit simplistic scales when density distribution functions (normal distribution for temperature or gamma-distribution for precipitation) shift unchanged to the left or right with climatic change and

Table 1 Different definitions of precipitation events at the upper end of its distribution (fitted to the eastern two thirds of the conterminous US territory). Decimal points are introduced to accommodate the British Empire unit system (inches) used in the US Meteorological practice instead of the SI system

Term used to describe a precipitation event at upper end of its distribution	*Daily and multiday precipitation events with the totals above (or within) selected thresholds based on*	
	Absolute values	*Upper percentiles*
Above 10 mm[a]	Above 10 mm	n/a
Intense	Above 12.7 mm	Above the upper 25%
Heavy	[12.7–76.2 mm]	Upper 10–5%
Annual maximum event total[b]	From 10 to 300 mm	Approximately the upper 1%; may vary broadly
Moderately heavy	[12.7–25.4 mm]	n/a
Very heavy	Above 75 mm	Above the upper 1%
Extreme	Above 150 mm	Above the upper 0.1%

[a] *This characteristic (threshold) was introduced by Frich (1999) for global assessments of 'extreme' precipitation. It can be used in cold climates (e.g., in the Arctic) where totals above 10 mm are indeed rare.*

[b] *This characteristic is commonly used in the hydrological and civil engineering communities.*

interpretation of 'increased/decreased' areas under the tail parts of these distributions are interpreted as extreme precipitation patterns changes. These changes have been nonlinear in many parts of the world. For example, (a) the increase of totals and the events frequency at the high end of precipitation distribution may be accompanied with a decrease in precipitation totals (cf., Easterling et al. 2000; Sun and Groisman 2000; **Figure 1**, top); (b) interseasonal precipitation events distribution can change its grouping (Zolina et al. 2010, 2012; **Figure 1**, bottom; Groisman and Knight 2007, 2008); (c) changes in intense precipitation of different genera can have different directions and rates (cf., Kunkel et al. 2012; **Figure 2**); and finally (d) within the high end of precipitation distribution a different sign of changes can be observed (cf., **Figure 3**).

Figures 2 and 3, as well as **Figures 11, 14, and 15** require a more detailed explanation as to how they were originated. At all stations, we selected only days (events) with intense precipitation (as defined above). Groisman et al. (2012) sorted these events and grouped them within seven intensity ranges. Thereafter, all intense precipitation data within each daily or multiday intensity range were summed, along with the correspondent peak hour intensity, number of days, and number of hours with nonzero precipitation during these days. From these tallies we calculated mean precipitation duration, mean daily, and maximum hourly intensity for the days (events) with precipitation for each intensity category. The same approach was applied to subsets of data for (a) the first 31 years and the last 31 years of our sample; (b) the warmest 31 (30) years and the coolest 31 (30) years during the 1948–2009 (2007) periods using the mean annual surface air temperature of the Northern Hemisphere (TNH), CONUS, central United States (T_{CUS}), and Gulf of Mexico (T_{Gulf}) as guidance; (c) intense precipitation derived from tropical cyclones (TC) in the hurricane season (June–November) and intense precipitation that originated without direct TC impact; (d) intense precipitation during various phases of the El Niño–Southern Oscillation (ENSO) cycle (El Niño, Neutral, and La Niña months); and (e) various other combinations and complements, e.g., warmest years versus coolest years for TC-originated precipitation and, separately for precipitation that was not originated from TCs, warmest years versus coolest years only for the hurricane-free season, warm season (May–October) temperatures for T_{CUS} and T_{Gulf}, minimum and maximum temperatures for T_{CUS}, etc. This approach generated a suite of estimates of climatology and changes with time, global and regional temperatures, rainfall genera, ENSO, etc., of intense precipitation events.

5.03.1.2.1 Focus on the Warm Season and Intense Rainfall

Frozen precipitation is critically important for the land surface hydrological cycle delivering a delayed (after snowmelt) contribution to runoff. In many parts of the extratropics and in the mountainous regions, intense snowmelt represents a major source of spring extreme events (floods). However, it is not important how it was accumulated throughout the cold season (daily or in a few extreme snow storms). Only the snow water equivalent remaining in the spring snowpack matters. Additionally, interruptions to transportation and other aspects of everyday human life in the regions of unstable and/or ephemeral seasonal snow cover can depend on a snowfall deficiency. Therefore, extreme prolonged no-precipitation intervals in the cold season are of less consequence as compared to the warm season. In the warm season, prolonged intervals without rain affect the entire biosphere and several critical aspects of human activity (agriculture, water consumption, river transportation, and hydropower production to mention a few). Moreover, in the warm season in the extratropics, prolonged no-rain periods correspond to anomalously high surface air temperatures due to the development of the soil moisture deficit and suppressed evapotranspiration. Together, rain deficit and hotter temperatures feed back to each other strengthening the hardship of the drought conditions (Mescherskaya et al. 2011; Barriopedro et al. 2011; Dai et al. 1998, 2004; USCCSP 2009). We shall describe the changes in the no-rain periods duration in subsection 5.03.2.9 Prolonged No-Rain Periods.

5.03.1.2.2 Cautious Note

Here, we outline an important feature of combination of increase in both frequencies, prolonged no-rain intervals and intense rainfall. Quite often hydrologists and climatologists use *dynamic* characteristics of heavy/high rain/streamflow events, such as annual maximum of daily rainfall (or peak streamflow). If these characteristics show systematic changes (trends), they claim an increase in heavy (or extreme) precipitation and streamflow. If these characteristics do not have trends, they argue that nothing has been changed, e.g., with flood frequency (cf., Lins and Slack 1999; Hirsch and Ryberg 2011). However, in the regions where both ends of the precipitation (streamflow) distribution are affected, we can observe a high flow (rainfall total) year followed by a low flow (rainfall total) year and maximum annual rainfall or peak streamflow (as well as any *dynamically* defined characteristic of the distributions tail based on the data of a single year) will vary widely without showing systematic changes. In Section 5.03.2, we show that this is the case in some regions of the world (including the eastern part of the CONUS; cf., also Semenov and Bengtsson 2002).

5.03.1.3 The Role of Daily Data in Analyses

Daily data are the most widely available for analyses (cf., Global Historical Climatology Network-Daily, http://www.ncdc.noaa.gov/oa/climate/ghcn-daily/). However, there is no reason to focus on single-day events only because intense precipitation events, except small-scale convective thunderstorms, have longer time scales. Even a short-term rain while beginning before the cessation time (which in many countries is not necessarily at midnight) can continue beyond this time, creating an impression that this is a 2-day-long event. To remedy this problem, different options were considered in studies of intense precipitation change. These include (a) consideration of 2-day (up to 5-day-long) rainfall totals (Kunkel et al. 1999, 2012; Groisman et al. 2001; Alexander et al. 2006), (b) a thorough documentation of the actual hours of begin and end of the rain events (Bonnin et al. 2004–2012), (c) assessment of the frequency of consecutive precipitation days (wet spells; Zolina et al. 2010, 2012) and consecutive intense rain days (intense rain events; Groisman et al. 2012), and (d) assessment of sequences of deep cyclones that one after another cross the region in a short time interval (e.g., in 2–3 weeks) with intense rains associated with them that first saturate soil and later fill all water bodies eventually causing disastrous floods (Lettenmaier et al. 2008; Kunkel et al. 2012).

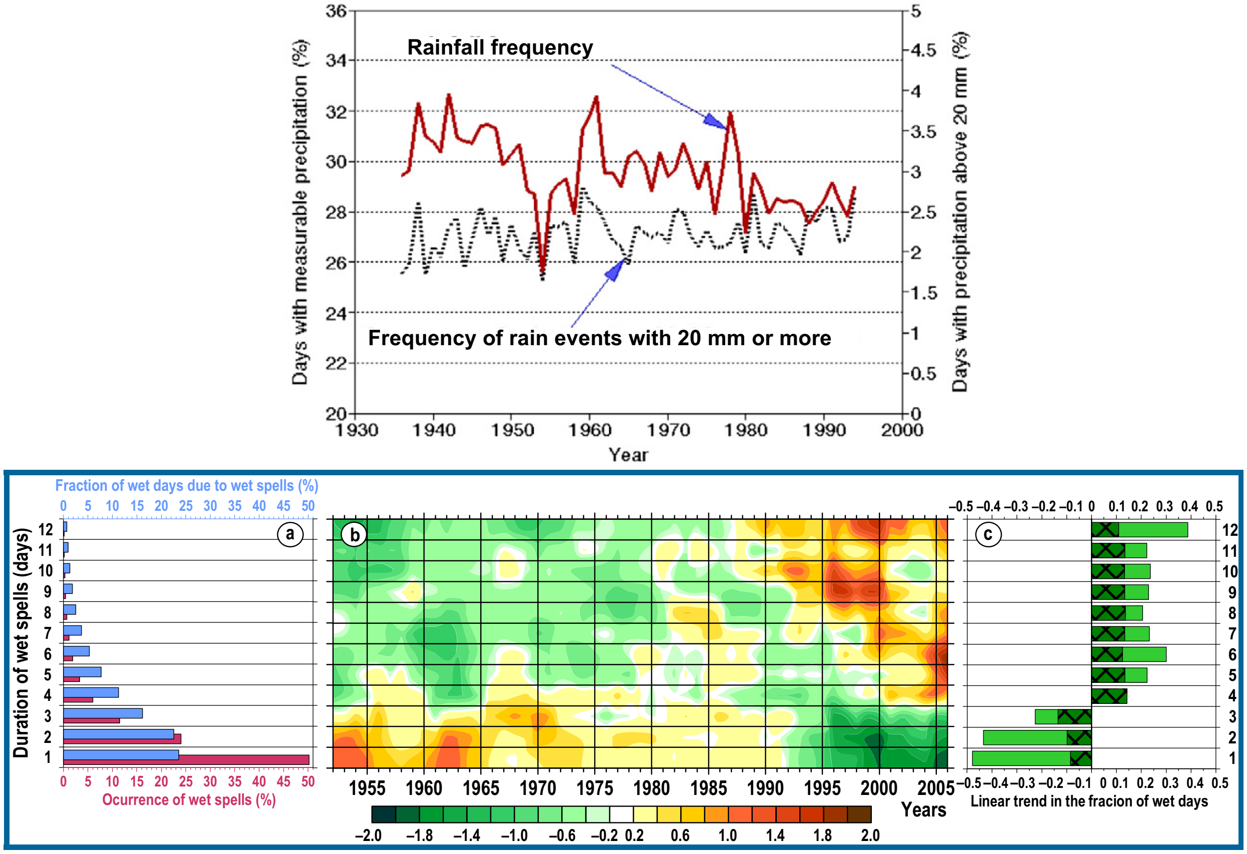

Figure 1 (Top) Summer frequency of rainy days and days with heavy rains over the Asian part of Russia (Sun, B., and P. Ya. Groisman, 2000: Cloudiness variations over the former Soviet Union. *Int. J. Climatol.*, **20**, 1097–1111.). In this part of the world, daily rainfall of 20 mm or above is considered as unusually heavy ('liven') and on average occurs approximately twice during the summer season. Bottom: Climatology of wet spells of different duration over Europe (a) climatology; (b) dynamics of changes with time; and (c) linear trends in the fraction of wet days (Adapted from Zolina, O., C. Simmer, S. K. Gulev, and S. Kollet, 2010: Changing structure of European precipitation: longer wet periods leading to more abundant rainfalls. *Geophys. Res. Lett.*, **37**, L06704. [Available online at http://dx.doi.org/10.1029/2010GL042468.]).

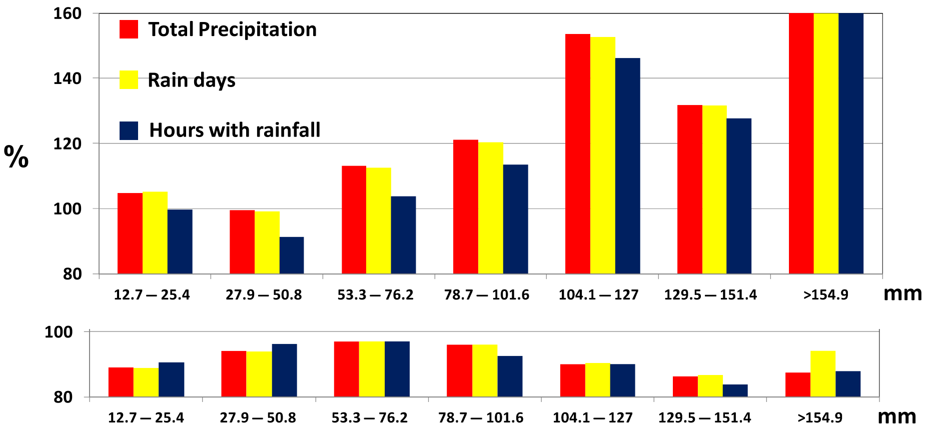

Figure 2 Comparison of intense precipitation characteristics during the June–November season over the southeastern United States associated with tropical cyclones (TC) for the 31 years of warmest and coldest Northern Hemisphere temperatures during the 1948–2009 period (top) and other not-associated with TC intense rainfall (bottom). Estimates of precipitation characteristics for these 31-year periods were averaged and their ratios (in percent per station) are shown sorted by day rainfall intensity ranges. The comparison shows that while the heavy rainfall characteristics associated with TC (up to extreme daily rain events above 154.9 mm) have increased over the southeastern United States during the last three decades, intense rain totals of other genera decreased (archive of Groisman et al. 2012).

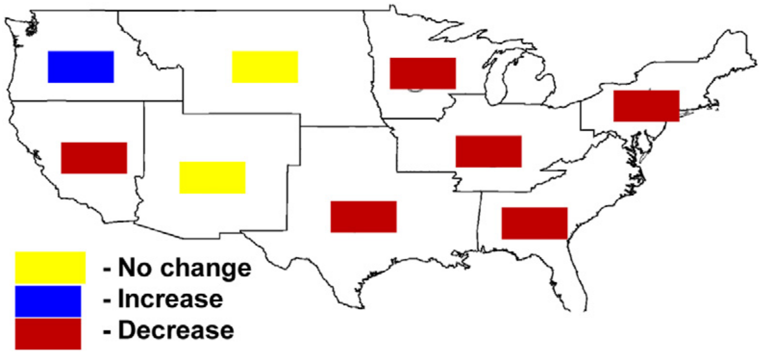

Figure 3 Changes with time, past three decades (1979–2009) versus previous period (1948–78) of the fraction of 'moderately heavy' precipitation (from 12.7 to 25.4 mm; or 0.5–1 inch) among all intense daily rain events above 12.7 mm over the contiguous United States. Annually among all daily rain events over the CONUS, 'intense' events (i.e., above 12.7 mm) comprise 25% of all days with precipitation but deliver more than 70% of rainfall. Among all intense events, days with moderately heavy precipitation are a majority (~75%) and deliver slightly more than a half of precipitation totals. The fraction of moderately intense precipitation within the intense precipitation spectra is shown to decrease over most of the CONUS (archive of Groisman et al. 2012). At the same time, very heavy precipitation is increasing over the eastern two/thirds of the CONUS (Groisman et al. 2004; USCCP 2009).

In Section 5.03.2, we present the observed changes in extreme precipitation during the past 50 years over the global land areas. To document 'observed' changes in rare precipitation events (extreme precipitation), one has to rely upon dense networks of many thousands of stations with long-term daily and hourly precipitation time series. However, these networks do not exist (or are not available to us) in some parts of the world. Therefore, referring to changes over 'global land,' we shall focus mostly on the extratropical land areas that are better covered by observations and on the regions/nations that openly share their data sets with the international scientific community. For some countries (e.g., for China, South Africa, and Japan), we are still able to perform our assessment using findings of national climatologists and hydrologists who have unrestricted access to the richest national hydrometeorological archives (cf., Zhang et al. 2011). For other countries (e.g., Poland), the international data centers either have no access to the volumetric national meteorological data or the national climatologists do not have permission to view and assess the complete daily data of the national hydrometeorological archive. Therefore, we had to omit the territories of these countries from consideration.

5.03.2 Observed Changes in Extreme Precipitation during the Past 50 Years over the Globe

5.03.2.1 Instrumental Precipitation Data Availability and Its Impact on Intense Precipitation Analyses

Each empirical study of extreme precipitation over a given region requires a dense network of meteorological stations (i.e., a network with high spatial resolution) with long-term precipitation time series at daily or sub-daily temporal resolution. There are several reasons for this requirement:

- A small scale spatial resolution of *some* precipitation extreme events (e.g., rainfall from summer thunderstorms has a typical radius of correlation of ~10 km; cf., Gandin et al. 1976). A sparse network of point measurements can easily miss the intense rainfall event or provide biased information about its peak intensity.
- Duration of intense rainfall or an intense phase of the prolonged rain event may be quite short (in many cases only a few hours) and assessment of precipitation totals for longer periods, e.g., monthly totals, may miss most of the features that make extreme precipitation so dangerous by causing flash floods in both urban and natural environments (cf., Changnon and Westcott 2002; http://www.nws.noaa.gov/hic/flood_stats/Flood_loss_time_series.shtml; Villarini et al. 2009; Robinson et al. 1998; Smith 2003). Furthermore, even the most violent rainfall can follow or be preceded by prolonged dry weather conditions and thus be virtually unnoticed within the totals.

Therefore, advances in accumulation and broad dissemination of the regional datasets that possess the above-mentioned properties closely correlate with our ability to document extreme precipitation events and to estimate their frequency, intensity, and changes in time and space.

As a vivid example, below we describe advances in studies of intense precipitation over the continuous US during the past 15 years. These studies used different methods and databases (Karl et al. 1997, 2009; Karl and Knight 1998; Easterling et al. 2000; Kunkel et al. 2003, 2007, 2010, 2012, 2013; Groisman et al. 1999, 2001, 2004, 2005; USCCSP 2009). The common feature in these data sets was the aggregation of precipitation to daily totals because, initially, there were no other reliable sources of climatological information on precipitation changes. The US Historical Climatology Network (that included initially 182 stations with daily data and now more than 1200 stations; http://cdiac.ornl.gov/epubs/ndp/ushcn/ushcn.html) was used by Karl and Knight (1998), Groisman et al. (1999), and Easterling et al. (2000) to assess the upper fifth percentile of stations' daily totals, the number of days with precipitation above 50.8 mm, and the changes in parameters of precipitation distribution with time. When the major archive of daily cooperative (COOP) stations was updated backward from 1948, the US climatologists were able to employ about

6000 daily time series over the United States and assess the century-long changes in very heavy precipitation events (in the upper 0.3 percentile of the precipitation distribution; cf., Groisman et al. 2004, 2005; USCCSP 2009). At each step, the advance was defined by new digital data sets of scientific quality that became available at that time and societal demand fueled by accelerated climatic changes and GCMs projections. The current concern is the possible changes in 'real' extremes, i.e., those that do endanger human life and/or well-being. These extremes are associated with very rare precipitation events. For example, days with rainfall totals above 154.9 mm over the hourly precipitation data (HPD) stations of the CONUS and US Midwestern states occurred once per 60 and 135 years, respectively. Using two independent precipitation data sets (HPD and COOP) and using the data only after World War II (which are much more numerous), it became possible to analyze the changes in the occurrence of these extreme events (Groisman et al. 2012).

Precipitation is the most closely monitored meteorological variable. The authors of the World Water Balance Assessment (WWB 1974) used climatological data from more than 100 000 individual rain gauge sites for their Assessment. At that time, focus was on monthly and longer time scales (cf., Legates 1987), and, to date, the major international center for precipitation data dissemination, Global Precipitation Climatology Center (Beck et al. 2005; http://gpcc.dwd.de/), archives and disseminates only the monthly precipitation data of approximately 45 000 stations. These data are disseminated in the gridded format due to restrictions imposed by the National Weather Services. Due to these restrictions, from present up to the last decade, daily data were infrequently used for large-scale precipitation change studies beyond the national boundaries. They remained preserved in different national archives worldwide. Since that time, attempts to assess precipitation changes at the daily and/or sub-daily time scales still have to rely on much smaller data collections. For example, the German and Mexican national archives store precipitation data from more than 7000 and 6000 stations, respectively, but they have not yet been tapped for international climate change assessments. For other nations, the situation is similar. An attempt to change this situation was launched several years ago with the establishment of the Global Historical Climatology Network-Daily (GHCN-Daily). Figure 4 shows the map of the meteorological stations density available in GHCN-Daily data collection for the past 60 years. This data set inherited all daily precipitation information available in the United States, Canada, and Australia, as well as several other national archives. The densest historical station networks come from the United States, Canada, and Australia – a reflection of the comprehensive contributions from these countries to GHCN-Daily. Nevertheless, Brazil, India, and South Africa have also contributed records from very dense national precipitation networks. For Europe, Russia, and China, the network contains only the stations designated for the international exchange by the national meteorological services of these countries.

GHCN-Daily is comprised of daily climate records from numerous sources that have been integrated and subjected to a common suite of quality assurance reviews (http://www.ncdc.noaa.gov/oa/climate/ghcn-daily/). The data set contains records from over 75 000 stations in 180 countries and territories. Numerous daily variables are provided, including maximum and minimum temperature, total daily precipitation, snowfall, and snow depth; however, about two thirds of the stations report precipitation only. The GHCN-Daily dataset is regularly reconstructed (usually every weekend) from its 20-plus data source components to ensure that GHCN-Daily is generally in sync with its growing list of constituent sources. During this process, quality assurance checks are applied to the full dataset. The interval covered by GHCN-Daily station records varies from less than 1 year up to over 175 years, with the average precipitation record lasting about 33 years. The updates are routinely conducted but with delays for most of the globe except the CONUS. The European, Australian, and Canadian data in GHCN-Daily are updated monthly, but for other countries the delays in the latest daily data can be substantial. Most of the new results presented below will be directly or indirectly based on GHCN-Daily. Under indirect use we mean the use of updated national data sets (e.g., for Russia and Mexico) that are currently in preparation for open access through GHCN-Daily but have already been used in our analyses. Included with results of analyses of intense rainfall, several national and regional analyses of changes in heavy and extreme precipitation will also be provided. At present, large-scale analyses of heavy (extreme) precipitation changes at the sub-daily (hourly) time scale are available only for the conterminous United States where a dense network of hourly precipitation (HPD; Figure 4(b)) has been operational for the past 100 years, and these data (so far, since 1948) have been recently digitized.

5.03.2.2 Instrumental Precipitation Data Problems across the Globe

Changes (especially at extreme intensities) fortunately are mostly unaffected by the impact of numerous changes in precipitation instrumentation and observational practices. The most serious problem that causes biases in measured precipitation is wind-induced turbulence over the gauge orifice (Sevruk 1982; Goodison et al. 1998; Adam and Lettenmaier 2003), which for intense rainfall can be ignored starting with the rate of above 2 mm h^{-1} (Bogdanova 1966; Sevruk 1982). For intense snowfall, the impact of wind on the rain gauge catch can be substantial (Figure 5). Therefore, traditionally when studying the precipitation changes in the regions with a substantial fraction of frozen precipitation relative changes are assessed, i.e., changes expressed in percent of the long-term mean or in percent of standard deviation, changes in return periods, etc. (cf., Karl and Knight 1998; Stone et al. 2000; Førland and Hanssen-Bauer 2000; Kattsov and Walsh, 2000; Zhai et al. 2005; Kunkel et al. 2009; Zhang et al. 2010).

Due to a greater ability of the warm atmosphere to hold moisture compared to the cold atmosphere, the highest values of precipitation over most of the globe are observed in liquid form and the focus on intense and extreme precipitation in this chapter allows us to skip the still unresolved issues of accuracy of frozen precipitation measurements as well as systematic changes in their biases. Instead, we describe two somewhat related problems in liquid precipitation measurements that can affect estimates of intense precipitation changes. The sensitivity of the rain gauges, i.e., their ability to report the lowest amounts of precipitation, can unexpectedly affect statistics of

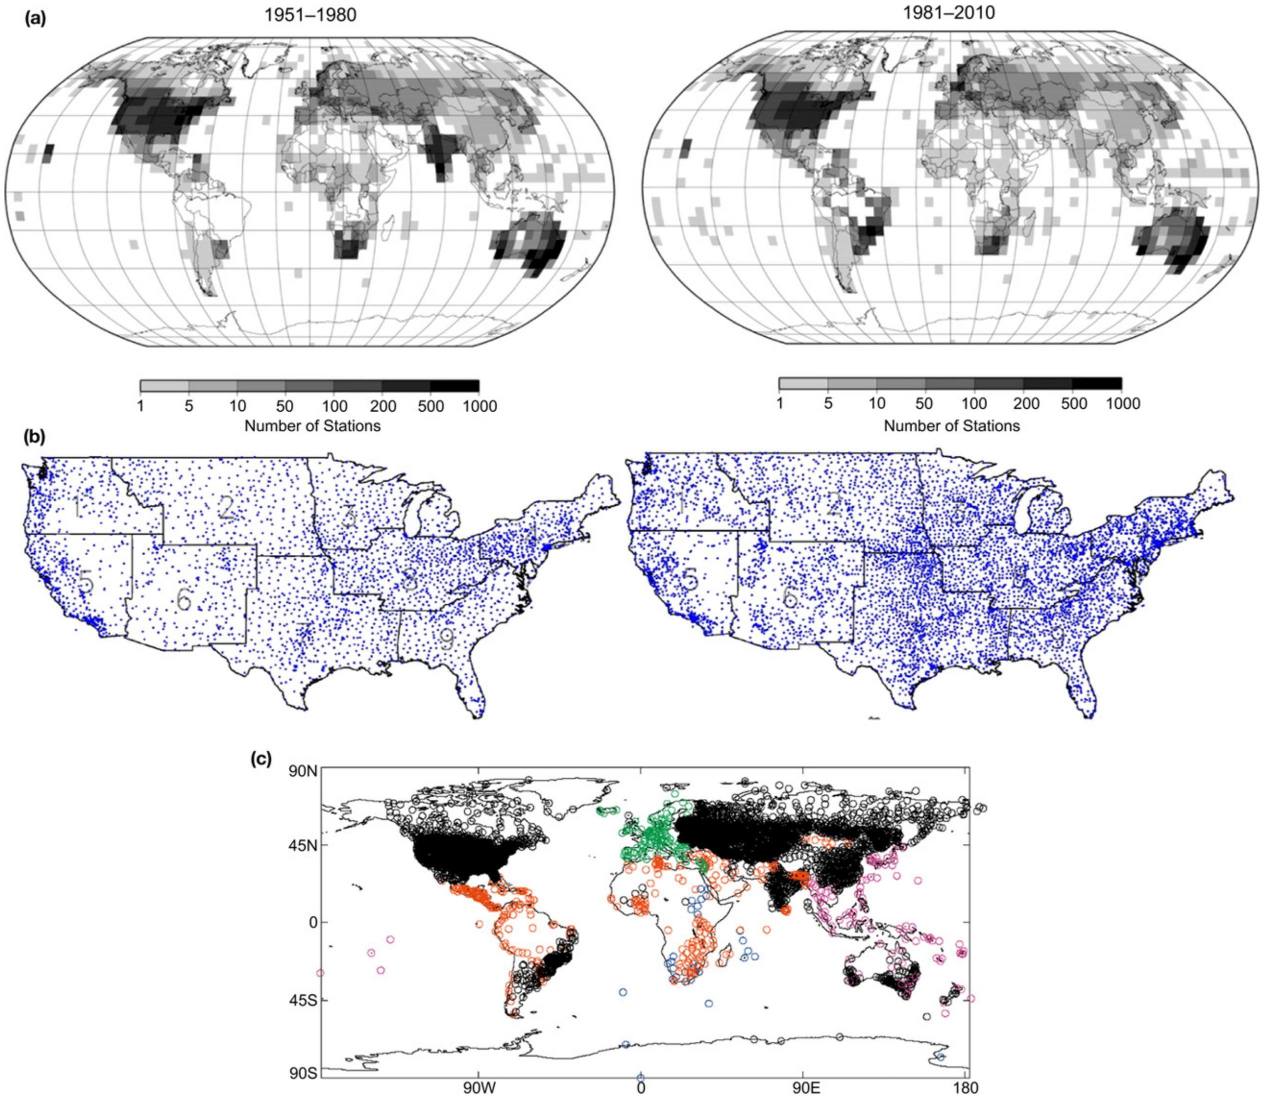

Figure 4 (a) Maps indicating the density of stations that have at least 10 years of precipitation records during the past successive 30-year intervals (source: http://www.ncdc.noaa.gov/oa/climate/ghcn-daily/). (b) Two station networks with long-term precipitation time series of hourly and daily precipitation available for the past 60 years over the CONUS. Blue dots on the maps show distribution of 3076 HPD stations (left) and 5885 long-term daily COOP observer stations (right), adapted from Groisman et al. (2004, 2012). Boundaries of regions used for area-averaged climatologies and change analyses in these studies are also shown. (c) Stations used in the recent near-global assessment of changes in intense precipitation (Alexander et al. 2006). Colors in this map are used to show the stations with daily precipitation from different sources. The largest of these sources (black dots) is GHCN-daily. Total number of stations is 5948.

rainfall intensity. First, we present a few examples and then discuss their consequences.

- In the late 1930s, the Norwegian Meteorological Service began sending letters of appreciation to its observers. In response, they began working even more diligently and reported each 0.1 mm of precipitation in their daily reports. Fifty years later, Groisman et al. (1999) found a significant century-long increasing trend in the number of wet days over this nation that was completely explained by a jump in the number of rainy days with 0.1 mm that were practically absent in the past records.
- In 1966–67, the Hydrometeorological Services of the former Soviet Union and later of Finland made concise efforts to account for light precipitation ‘to the last drop’ and introduced wetting corrections to each nonzero precipitation measurement (0.2 mm for liquid and 0.1 mm for frozen precipitation; when at least one drop was extracted from the gauge it was assumed to be a 0.1 mm). The number of days with precipitation increased and the total reported precipitation increased by 5–10% and up to 30% in the Arctic regions (Shver 1976; Groisman and Rankova 2001).
- After Canada switched from British units to SI (for precipitation, the measure changed to mm instead of 0.01 inch), all statistics of rainfall and snowfall occurrence became ‘slightly’ incomparable. This and several changes in instrumentation (cf., Metcalfe et al. 1997; Mekis and Hogg 1999) made it very difficult to assess changes in the light

Figure 5 Major instrument and/or methodology changes at the national precipitation network of several countries of the Northern Hemisphere and average order of biases (inhomogeneities) caused by these changes (Karl, T. R., R. G. Quayle, and P. Ya. Groisman, 1993: Detecting climate variations and change: new challenges for observing and data management systems. *J. Clim.*, **6**, 1481–1494.).

precipitation occurrence over this nation (let us recall that even in southern Canada the median daily precipitation total is on the order of 1 mm).

Figure 6 illustrates the inhomogeneity of information stored in the US and Canadian digital archives regarding the low intensity precipitation. For example, in the United States, the number of 0.01 inch precipitation reports steadily grew from 6 to 13 year^{-1}. Reports of 0.02 and 0.03 inch daily precipitation remained steady since the 1940s but prior to these years they were also less frequently reported. During the 1961–90 period, on average, there were 88 days with nonzero precipitation nationwide and ~19 of them (22%) reported from 0.01 to 0.03 inches of precipitation. In the beginning of the twentieth century, these numbers were close to 11 days and 100 years later exceeded the 20 days threshold, i.e., nearly doubled. In the

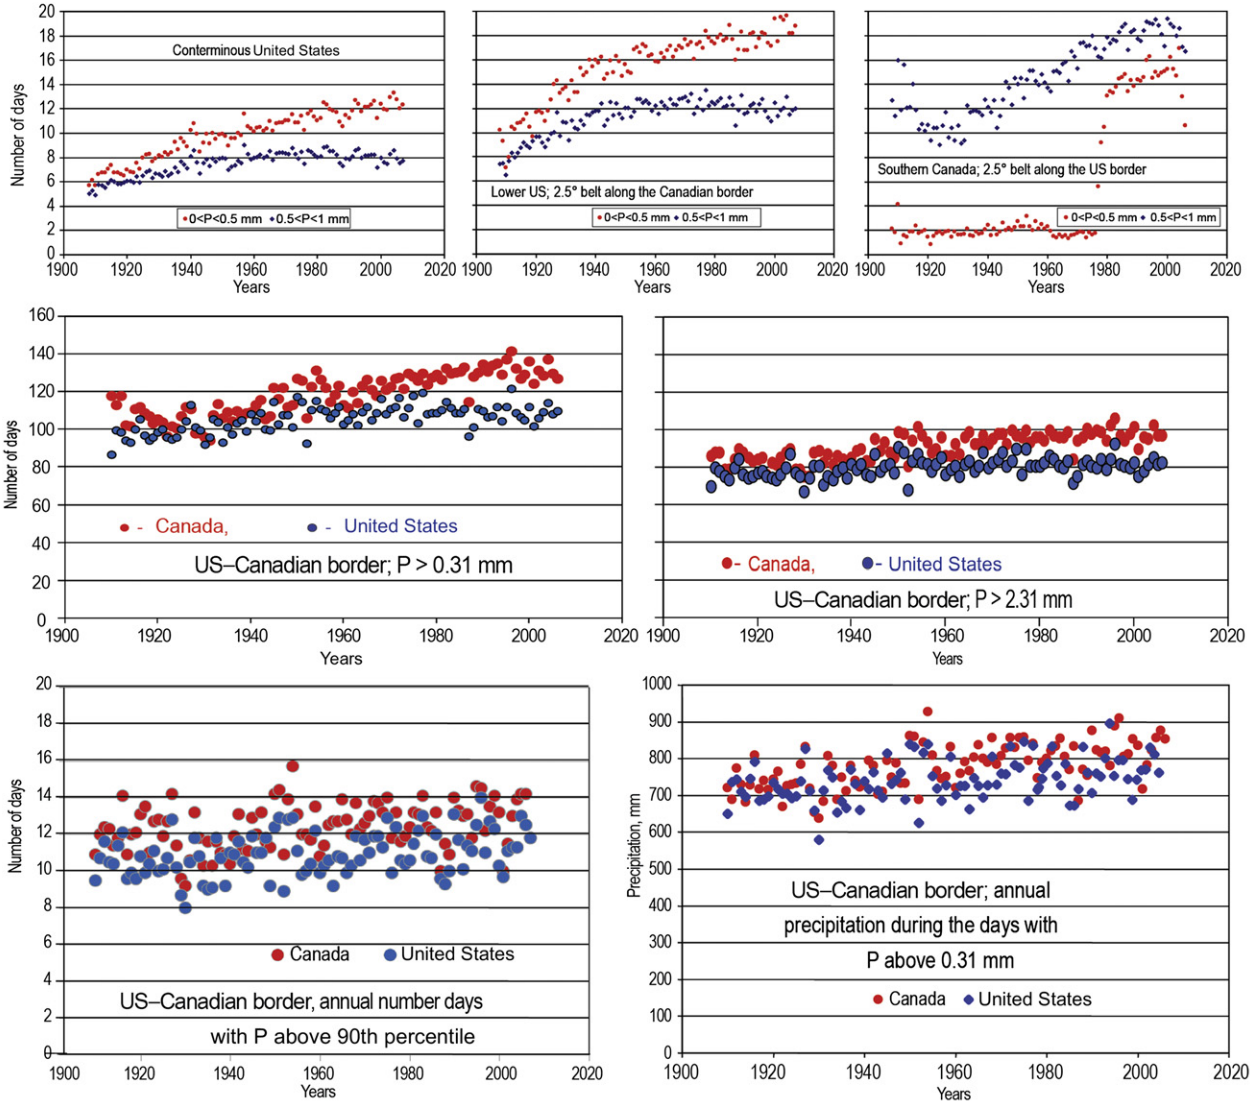

Figure 6 (Top panel) Mean number of days with nonzero very light daily precipitation over the conterminous United States (left; Groisman and Knight 2007, 2008) and along the 2.5° latitudinal belt along the US–Canadian border, US (center) and Canadian (right) sides of the border. (Middle panels) Annual number of days across the US–Canadian border (±2.5°lat.) with precipitation (left) above 0.31 mm and (right) above 2.31 mm. Blue and red dots show the US and Canadian precipitation frequency, respectively. Note the difference in trends, first of all, for Canada. (Bottom panels) Annual number of days across the US–Canadian border (±2.5°lat.) with heavy precipitation (upper 10th percentile; left) and precipitation totals for days with P above 0.31 mm (right). Blue and red dots show the US and Canadian precipitation frequency, respectively. Due to station network paucity, only the border between the conterminous U.S. and southern Canada are assessed in all graphs of this Figure.

northern United States along the Canadian border the effect is even more pronounced. During the 1961–90 period, on average, there were 118 days with nonzero precipitation and ~30 of them (25%) reported from 0.01 to 0.03 inches of precipitation. Since the beginning of the twentieth century, the number of reported 0.01-inchers nearly doubled and the number of reported 0.02- and 0.03-inchers increased from ~8 to ~12 in the 1940s and remained steady thereafter.

We actually expected this problem only on the Canadian side of the border (cf., Vincent and Mekis 2006). These authors reported very large trends in the number of days with precipitation entirely across Canada treating them as a true finding. We hypothesized that this is a result of the changing of instrumentation and observing practices in Canada (Groisman et al. 2003). Figure 6 (top panel) supports this, our claim, and illustrates the inhomogeneity of information stored in the Canadian digital archives for the southernmost part of the country along the US border. Here, the number of daily precipitation reports of less than 0.5 mm increased from 2 to 14 year^{-1} after the introduction of metric (instead of British) units and rain gauges with a transparent bucket. The number of reports of daily precipitation in the interval within 0.5–1.0 mm interval in this part of Canada has also changed during the past 100 years by 90% from ~10 to ~19 year^{-1}.

After encountering the problem with low intensity precipitation reporting, it is worthwhile to sacrifice the low precipitation daily bins (in any case, they were not consistently reported during the past century) and to find the thresholds (cutoff breakpoints) after which we can reliably analyze time series of 'days with sizable precipitation' (i.e., days with precipitation above these thresholds) as well as precipitation totals over southern Canada. Various cutoff breakpoints were used to eliminate a range of smaller values from the analyses of 'days with precipitation.' Below, we show an empirical approach to assure that there is a possibility to assess the 'sizeable' precipitation trends even in the presence of the inhomogeneities reported in Figure 6.

We discarded the day with precipitation below 0.01″ (using cutoff value 0.31 mm), and compared the trends across the border. Then, we incremented the cutoff value by another 0.01″, etc., up to days with precipitation below 0.1″ (or 2.6 mm) from both sides of the border and compared trends for the past century. We did not see problems with the US trends (very soon they became invariant to the breakpoint selection). But, for southern Canada, in order to extract what appear to be reasonable trends (i.e., similar to those observed in a close southward proximity), it was found that only the value 2.31 mm (which eliminates 0.09″ and lower daily precipitation events) is a safe value along the entire border (Figure 6, middle panels). Further testing indicates that it is possible to use smaller cutoff points for days with precipitation, if we are intending to analyze the data only after 1978–80 (the years when most of the changes causing homogeneity problems last occurred in the Canadian observation practice). Similar analyses performed for total precipitation and for days with heavy (upper 10th percentile) and very heavy (upper first percentile, not shown) precipitation show that the 'breakpoint' problem is not acute and does not create changes between the slopes of trends across the US–Canadian border (Figure 6, bottom panels).

Any analysis of temporal changes in the HPD data has to account for one important change at the network since 1960s: From 1948 to 1960, all of the gauges recorded with a resolution of 0.254 mm (0.01 inch). These gauges were gradually replaced so that currently more than 85% of HPD gauges record to a resolution of 2.54 mm. Fortunately, this gradual replacement of gauges is well documented and it is possible to homogenize the time series (cf., Groisman et al. 2012) for the entire period of record. This conversion is of critical importance. Without this adjustment for gauge resolution, an unaware user could generate grossly false conclusions about the changes in precipitation duration and intensity. The accuracy of the COOP network rain gauges has remained 0.254 mm throughout the entire period of observations.

All of the above have one problem in common: instability of reporting of light precipitation (in the daily and hourly totals). The researchers who intend to assess the upper tail of the precipitation distribution using upper percentiles, can be hurt from the low end of this distribution because

- estimates of the number of observed no-rain days and estimates of 'daily intensity' (precipitation totals divided by the number of days with precipitation) can be contaminated by artificial trends;
- on the hourly time scale, estimates of the rainfall duration and intensity trends can be extraordinarily high (and opposite in sign) if the resolution of the gauges changes with time;
- the attempts to estimate the daily precipitation distribution (e.g., with gamma-distribution) and its changes with time can be affected by the changing numbers of low values that are close to zero (which, over most of extratropics, are the most frequent precipitation events); the following assessment of the upper tail of this distribution and its changes will be in trouble; and finally,
- the upper percentiles of daily precipitation each year can be based on a very different fraction of rain days (cf., Figure 6).

Different ways to handle this problem can be found in Groisman et al. 1999, 2012; Rosenberg et al. 2010; and Mishra et al. 2012.

The last (less frequent) data problem that may affect researchers who study heavy precipitation is a changing amount of the accumulated daily precipitation totals with time. So far, we found only one country (Australia, cf., Groisman et al. 1999) where this problem is sufficiently severe and had to be resolved prior to further analyses of heavy precipitation changes. When the post offices in this country switched from a 6- to 5-day work week schedule, a substantial part of the national precipitation network located at these offices began reporting Monday extreme rainfall and the previous days were missing.

5.03.2.3 Geographical Distribution of Changes in Intense Precipitation

Approximately 15 years ago, studies of global-wide changes of intense precipitation were virtually absent because the appropriate data sets did not exist (i.e., long-term time series with daily and/or hourly resolution from dense international networks of meteorological stations). National data sets existed but they were not shared simply because there appeared to be little interest in working with them. The situation gradually changed after first reports about potentially dangerous tendencies of increasing of intense rainfall in the upper percentiles of its daily distribution (Iwashima and Yamatomo 1993; Karl and Knight 1998) and theoretical expectations of further development of these tendencies in the warmer climate were projected with human-induced changes in the atmospheric composition (Meehl et al. 2007).

Initially, the number of stations used in these analyses was quite modest. For example, the first daily station data set employed by Karl and Knight (1998) included the long-term daily precipitation time series of only 182 stations over the CONUS (compared to more than 6000 stations used in the present national analyses such as USCCSP 2009). This paucity of stations, in turn, allowed analyses of intense precipitation only above the upper fifth percentile or annual/monthly maximum rainfall that (a) did not qualify to be truly extreme events and (b) in the case of annual maximum, can be misleading in the regions where precipitation changed at both ends of its distribution (cf., *Cautious Note* in Section 5.03.1.2.2). It became clear that without preparation of expansive international precipitation data sets with daily time resolution, no further advance would be possible. First efforts to compile such data sets were made at the US National Center for Atmospheric Research (Spangler and Jenne 1984; Liebmann et al. 1999,

2001) and the NOAA National Climatic Data Center (NCDC; cf., http://www.ncdc.noaa.gov/oa/gsod.html; http://www.ncdc.noaa.gov/oa/climate/ghcn-daily/). These efforts were supported by the World Meteorological Organization with organizing regional workshops devoted to analyses of regional daily data. During the 1998–2008 period, 16 such workshops were organized (Peterson and Manton 2008) and their results were later reworked into scientific papers (cf., Peterson et al. 2002; Easterling et al. 2003; Aguilar et al. 2005, 2009; Sensoy et al. 2007; etc.). Furthermore, NCDC invited scientists from different countries who have expertise (and access to scientific quality national data sets) to visit the Center for joint data quality analyses (e.g., Groisman and Rankova 2001; Ren et al. 2005) and joint assessments of changes in heavy precipitation (Groisman et al. 1999, 2005; Easterling et al. 2000; Groisman et al. 2005; Alexander et al. 2006). Gradually, from these studies a mosaic of systematic changes in intense precipitation over the globe was compiled and revealed several systematic features of changes in intense and heavy precipitation (Figure 7).

- Over most of the extratropics in the rainy season with the highest rainfall, intense precipitation (rain events in the highest upper percentiles of daily distribution) became more frequent during the past 50–60 years.
- In the tropical zone, the sign of changes varies; there are regions where heavy precipitation frequencies increased and other regions where they decreased.
- If there was a significant increase in mean seasonal precipitation, the increase in the upper percentiles (heavy precipitation) was disproportionally large compared to changes in mean precipitation.
- In several large regions (e.g., northern Asia, Mediterranean, central Mexico) where the mean precipitation did not change or even decreased, the heavy precipitation events nevertheless became more frequent.

Figure 7 is a third generation of the picture first presented in Easterling et al. (2000) and thereafter in Groisman et al. (2005), where signs (+ and −) show the regions with observed changes in heavy precipitation that follow the pattern outlined above: changes in mean precipitation are less or insignificant, while changes in heavy/very heavy precipitation are statistically significant. Initially, the shading on the map indicated the countries for which the authors' team had and analyzed the data themselves, but gradually the distinction became only historical because other scientists have studied most of these regions as well and reached similar conclusions. While there were efforts to unify the definitions used to characterize intense (heavy, extreme) precipitation over the globe (cf., Frich et al. 2002), they cannot be considered successful. Different research agendas faced by the scientists in different countries and different disciplines (civil engineers, hydrologists, climatologists, and agriculturists), and the different amounts of data they had to address these agendas actually dictated the selection of thresholds used for definitions of terminology of intense precipitation categories (cf., discussion in Section 5.03.1.2 Definitions of Intense Precipitation). Therefore, the regional results that we shall describe below are diverse and thus require individual description.

Moreover, according to our classification in Table 1, most of these results are devoted to changes in the frequency of heavy and very heavy precipitation events but not of extreme events (although the authors frequently name them 'extremes,' e.g., the upper 5% of daily rainfall distribution or the annual maximum rainfall). We again have to warn about the use of 'dynamic' definitions when, for each year, the high end of daily rainfall distribution is selected to characterize very heavy and/or extreme rain events. In dry years, these events may be 'not at all heavy or extreme,' and in some regions may hide the actual changes at the high end of the daily rainfall distribution (cf., *Cautious note* in Section 5.03.1.2.2 Cautious Note).

5.03.2.4 Updated Analyses for Several Large Regions of the Northern Extratropics

Below, we decipher signs presented in Figure 7 as they were first presented in Groisman et al. (2005), updating and/or supporting them with results of other studies.

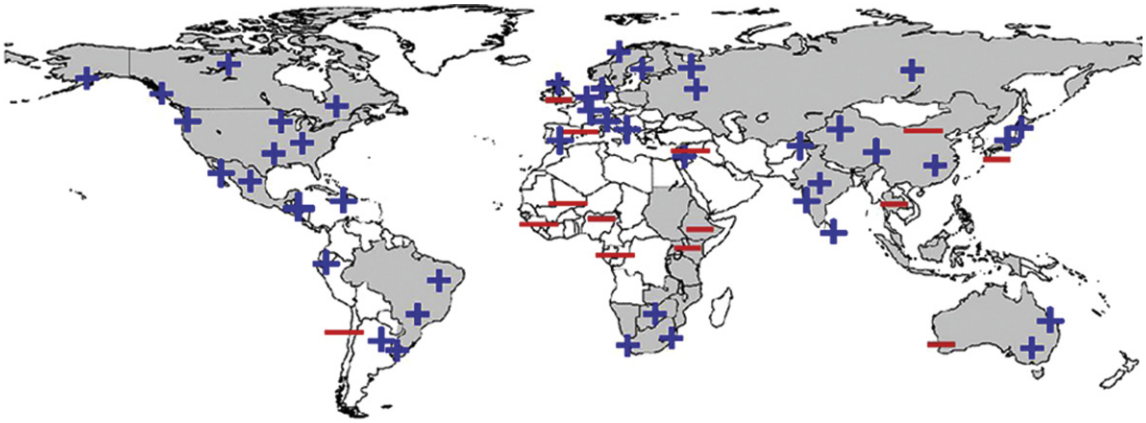

Figure 7 Regions where disproportionate changes in heavy and very heavy precipitation during the past decades were documented compared to the change in the annual and/or seasonal precipitation (Easterling et al. 2000; Groisman et al. 2005; substantially updated first in Trenberth et al. 2007 and for the present chapter). Thresholds used to define heavy and very heavy precipitation vary by season and region. However, changes in heavy precipitation frequencies are always higher than changes in precipitation totals, and, in some regions, an increase in heavy and/or very heavy precipitation occurred while no change or even a decrease in precipitation totals was observed.

5.03.2.4.1 European Part of the Russian Federation

In the European part of the former USSR, more than 700 long-term stations during the period 1936–97 were available to Groisman et al. (2005) for analyses of 'heavy,' 'very heavy,' and extreme precipitation defined as upper 5–10% (heavy), 1–0.3% (very heavy), and 0.1% (extreme), respectively. Most of the newly independent states of this territory (except Russia and Belarus) do not share sufficient volume of their meteorological observations with international archives. Therefore, now for similar analysis during the period 1936–2010 in the European part of the Russian Federation, we can use the data of 335 long-term Russian stations. In general, maximum precipitation in this area occurs during the warm season, with very heavy rainfall coming almost entirely from convective clouds (Sun et al. 2001). Note that approximately 95% of the daily precipitation events are still less than 10 mm day^{-1}. **Table 2** presents the results of trend analyses for these two regions for the summer season. Both show a large increase of about 10% in summer precipitation in the region for the study period although the century-long increase is smaller (e.g., Groisman and Rankova 2001). During the same period, the rate of increase in heavy precipitation, in very heavy precipitation and in extreme rainfall, was higher than for mean summer precipitation (for the summer season, we use here a 0.3 percentile as a threshold to define extreme rain events that occur in these two regions approximately once in 10 years). The linear trend of the time series of heavy precipitation was statistically significant at the 0.01 level in both regions. In the southern region, trends in very heavy (upper 1% of rain events) and even in extreme *annual* precipitation are also statistically significant at the 0.05 level or above for the former USSR during the period 1936–97. For the extended period 1936–2010, the sign and absolute values of trends in very heavy and extreme *summer* precipitation became statistically insignificant. An updated precipitation time series for this region shows a continuation of the precipitation increase as well as the increase of the frequency of intense rain events of various strengths up to 2009. The rates of change did not appreciably change compared to the annual events for the shorter period, but the thresholds and the level of interannual variability of the area-averaged number of days with heavy and extreme summer rainfall are higher than those for precipitation during the entire year. Moreover, in 2010, a dramatic summer drought (cf., Mescherskaya et al. 2011; Barriopedro et al. 2011) contributed to this variability. It did not reverse the trends in the frequency of heavy, very heavy, and extreme rain events in this part of the world but zero values as the last points of time series of very heavy and extreme rain event counts did not add to trend estimates either.

5.03.2.4.2 Fennoscandia

Fennoscandia is very well covered by precipitation stations (**Figure 4**), but only a fraction of the daily data for this network is publicly available (Klein Tank et al. 2002), or for special research projects such as Arctic Climate Impact Assessment (ACIA 2005). There were previous reports describing the total precipitation increase in northern Europe (Hanssen-Bauer et al. 1997; Heino et al. 1999; Førland and Hanssen-Bauer, 2000; Folland and Karl 2001), but they all reported a smaller relative change compared to Groisman et al. (2005) for changes in 'very heavy' precipitation frequency defined as the upper 0.3% of daily precipitation events both in summer (a season with the most intense precipitation) and throughout the year (**Figure 8**). All increases have occurred since the 1980s. The average regional upper 0.3% thresholds are 50 and 45 mm for summer and annual, respectively.

A 66% increase to the early 2010s of the summer frequency of very heavy daily rain events (a region-wide average of 50 mm, but along the Norwegian Sea Coast it was much higher), which in the early 1950s approximately occurred once per decade, became a large problem because it coincided with changes in an intra-season distribution of the rainy days. Recently for Norway, Zolina et al. (2012), after analysis of the daily data of more than 200 national stations, showed a simultaneous shortening of wet periods for the past 60 years in southern Norway along the Sea Coast in the warm season, and a significant increase in the cold season. This implies that while the winter precipitation can

Table 2 Trend characteristics of the summer precipitation for the western part of the Russian Federation over the period 1936–2010. Mean totals and the number of days with precipitation above upper percentile thresholds. Trend values statistically significant at the 0.05 level or at the 0.01 level are marked with asterisks (*) and double asterisks (**), respectively (updated archive of Groisman et al. 2005).

Extreme	99.7th percentile	0.10	38	18	3

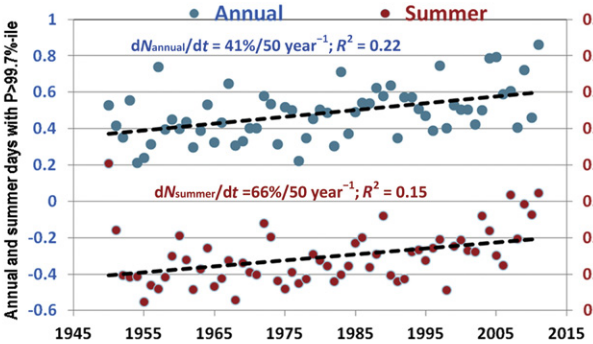

Figure 8 Frequency of very heavy (above the upper 0.3 percentile) annual (blue) and summer (dark red) daily precipitation events during the 1950–2011 period over Fennoscandia. All linear trends (shown by dashed lines) are statistically significant at the 0.01 level or above (updated time series from Groisman et al. 2005). Mean regional numbers were produced by the arithmetic averaging of the actual stations' numbers of days with very heavy precipitation within the 1 × 1 grid cells with the appropriate area-weights averaging of the grid cell values.

be more equally spread within the larger wet spells, in summer, intensity of daily rainfall should disproportionally rise (as predicted by Groisman et al. 1999) and is shown in Figure 8. It is worthwhile to note that the summer precipitation totals area-averaged over Fennoscandia did not change during the past 60 years. During the past 60 years, annual totals of *measured* precipitation over Fennoscandia have increased with a mean rate of 30 mm per decade. Part of these increases is real, but a sizeable fraction of increase is due to a better snowfall catch of the new Finnish gauges (Figure 5) and a general shift in the ratio between liquid and frozen forms of precipitation with regional warming (all contemporary rain gauges catch a larger fraction of rainfall than of snowfall; cf., Førland and Hanssen-Bauer 2000; Goodison et al. 1998).

5.03.2.4.3 Canada

Stone et al. (2000), while analyzing heavy precipitation over Canada, had to account for restrictions imposed by frequent low intensity precipitation over most of the nation with respect to the definition of heavy precipitation. They argue that when the upper decile of daily precipitation events can correspond to a threshold of ∼0.5 mm, it is difficult to consider these events 'heavy' (e.g., in northern Canada). Furthermore, our analysis (cf., Figure 6) shows that the analysis of frequent light precipitation events in Canada is challenging, but when looking for precipitation above 5 mm day^{-1} the process is trouble-free entirely across Canada. Fortunately, Stone et al. (2000), in their definition of heavy precipitation, used this value as a minimum threshold ($T_5 = 5\ \text{mm day}^{-1}\ (1 + n)$, where $n = 0, 1, 2$, etc.; the n-values were individually selected at each station in order to secure at least five events per year in each 3-month-long season of the 1960–90 reference period). Such sophisticated selection allowed them to analyze the changes of sizeable precipitation events at the upper end of the daily distribution across the entire nation that (a) are all above 5 mm and (b) consider on average approximately 20 precipitation events per year as heavy events. The authors grouped their stations into five large regions with similar patterns of precipitation changes (southeast, northeast, Arctic Canada, southwest, and northwest). The frequency of thus defined heavy precipitation events during the analyzed period of 1950–95 increased over the densest populated part of Canada, the *southeast*, in the spring–summer season (April through August). This region is relatively humid (thus, the selected n-values there were among the highest in the nation). Over *northeastern Canada* they reported an increase in heavy precipitation in the spring months and in the last 5 months of the year. Over *Arctic Canada*, heavy events frequency increased significantly during most of the year (except the summer months). Over *northwestern Canada*, heavy precipitation events increased in winter and spring, while no changes in heavy precipitation were documented in *southwestern Canada* in any 3-month-long part of the annual cycle. It is notable that no large region across the nation was found to have a 3-month-interval where statistically significant decreases in heavy precipitation were documented during the 1950–95 period (Stone et al. 2000).

5.03.2.4.4 Pacific Coast of Northwestern North America

The Pacific coast of northwestern North America is the only large high latitude region with both large annual precipitation totals and a sufficiently dense precipitation network available for our analyses in the Western Hemisphere. The mountainous character of these two regions makes the heavy precipitation here an important issue because of the landslide and flash flood danger. Figure 9 shows the time series of the frequency of heavy and very heavy precipitation in southern Alaska (south of 62°N) and British Columbia, Canada (BC; south of 55°N). These time series were first presented by Groisman et al. (2005) and here they are updated to 2010. In both regions, precipitation increased during the period of record, but the double-digit increases in the frequency of heavy and very heavy precipitation are especially noteworthy (Table 3). Given the high thresholds for these events, these changes reflect an increasing societal and/or environmental threat in both areas. Note that in southern Alaska in the last 8 years, the frequency of very heavy precipitation returned to long-term mean values and the trend of their occurrence is statistically insignificant.

5.03.2.4.5 Mexico

Analyzing variability of the heavy daily precipitation occurrence (upper 10 and 5% of daily rain events mostly in the winter season) in northern Baja California during the 1950–2000 period, Cavazos and Rivas (2004) linked this occurrence to the strong impact of El Niño events and neutral ENSO conditions in the region. While linking most of the variability to ENSO and tropical moisture transport into the region associated with El Niño 'pineapple express,' they also documented a shift of heavy precipitation distribution, with a relatively dry period and less variability during 1950–76, followed by a relatively wet period and more variability during 1976–2000. Variability in this dry region means more frequent heavy rain events, some of which caused flooding and losses of life in the city of Tijuana. Southward, over the central Mexican Plateau, the changes in summer heavy

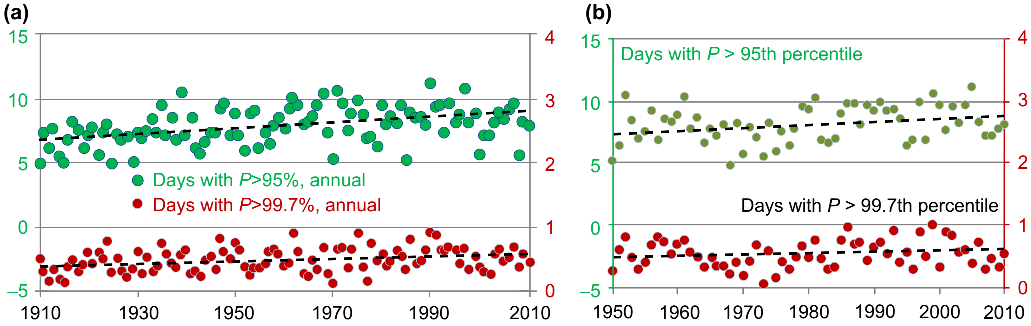

Figure 9 Heavy and very heavy annual precipitation variations and linear trends along the northwestern coast of North America (a) British Columbia south of 55°N and (b) Alaska south of 62°N. Statistical significance of linear trends is provided in **Table 3**. Mean regional numbers were produced by the arithmetic averaging of the actual stations' numbers of days with heavy and very heavy precipitation within the 1 × 1 grid cells with the appropriate area-weights averaging of the grid cell values.

Table 3 Heavy and very heavy annual precipitation along the northwestern coast of North America. Values of mean annual precipitation, area-averaged thresholds for heavy (upper fifth percentile) and very heavy (upper 0.3 percentile) are shown. Trend estimates in total precipitation and annual number of days above the two thresholds are also presented. Trend values statistically significant at the 0.05 level or at the 0.01 level are marked with asterisks (*) and double asterisks (**), respectively.

	Total precipitation		*95th percentile threshold*		*99.7th percentile threshold*	
Region, Period assessed	*Mean mm*	*Trend % 50 year^{-1}*	*Value mm*	*Trend % 50 year^{-1}*	*Value mm*	*Trend % 50 year^{-1}*
British Columbia, south of 55° N 1910–2010	1625	6.1**	26	12**	56	16**
Alaska, south of 62° N 1950–2010	1635	6.8*	28	13*	66	17

precipitation (the upper 5% of daily rain events or those above the 25–35 mm thresholds) followed the change of the mean precipitation that was decreasing in the last three decades prior to year 2005 (Groisman et al. 2005). However, the frequency of very heavy precipitation (above the upper 1 and 0.3% of the rain events or above 55 and 75 mm, respectively) increased during the same 30-year-long period. The frequency of very heavy rain events (above the upper 0.3%) has substantially increased (by 110% per 30 years). Thus, while in the early 1970s, the average return period of such events was approximately 12 years; in the early 2000s it is estimated to be around 5 years.

5.03.2.4.6 Contiguous United States

Studies of the changes in heavy and very heavy precipitation over the CONUS (cf., Karl and Knight 1998; Groisman et al. 2001, 2004, 2005; Kunkel et al. 1999, 2003, 2007) were summarized in USCCSP (2009) and Karl et al. (2009). In these National Assessments it was shown that over the entire eastern two-thirds of the CONUS, daily and multiday precipitation events became more frequent and the most prominent increases occurred over the northeastern quadrant of the CONUS (Figure 10).

In the southeastern United States very heavy and extreme precipitation associated with tropical storms and hurricanes has increased (Knight and Davis 2009; Kunkel et al. 2010; Wang et al. 2010), while other intense rainfall occurred less frequently in the past decades (archive of Groisman et al. 2012; Figure 2). This development allowed Wang et al. (2010) to conclude that during the 1948–2007 period, the southeast summer rainfall exhibited higher interannual variability with more intense summer droughts and anomalous wetness in the second 30 years (1978–2007) than in the prior 30 years (1948–77).

For the eastern regions of the CONUS, the recent elevated numbers are the largest since reliable records began in 1895. For western regions, the recent decades are comparable to the early part of the historical record.

For the past three decades, *in the central United States*, Groisman et al. (2012) reported a considerable increase in very heavy and extreme rainfall (up to 40% increase for daily and multidaily events above 155 mm or 6 inches; Figure 11). However (after checking all other possible causes in addition to the ongoing global warming), they hypothesized that at least a part of this tremendous rise in extreme rainfall might be associated with local anthropogenic forcing, intensification of land use, and doubling and/or quadrupling of corn and soybeans yield in the area.

In addition to the frequency changes of intense precipitation, its intensity has increased over the entire CONUS. Figure 12 (top) shows nationwide changes in intense precipitation that comes in fixed 1- and 2-day-long strings of consecutive rain days (defined here as a day with daily total above 12.7 mm or 0.5 inch). Together, 1- and 2-day-long strings represent 97.5% of all intense rainfall days and deliver 93% of its precipitation. Over the Midwest, the rainfall that comes in 3- and 4-day-long consecutive days has also significantly increased (Figure 12, bottom). In this part of the United States, frequency of the 4-day-long consecutive rainfall events (that comprise *on*

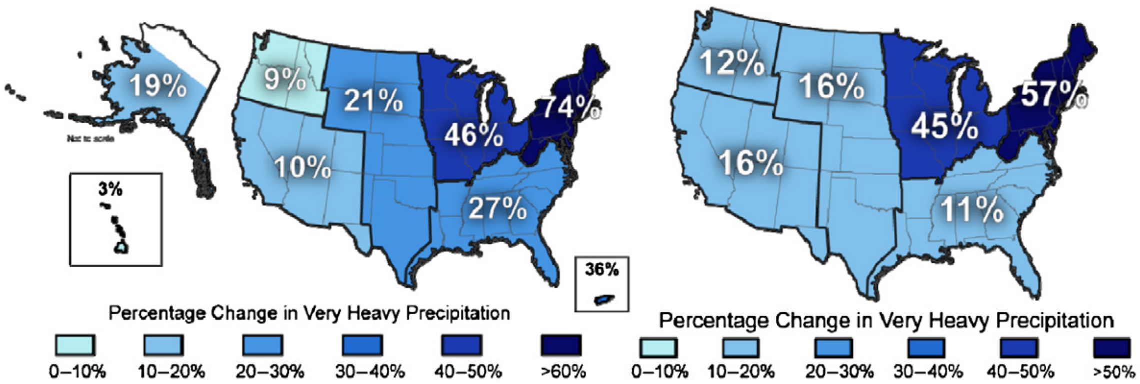

Figure 10 Observed increases in very heavy precipitation during the 1958–2010/11 (update of similar finding presented in Karl et al. 2009). (Left) Percent increases in the annual amount falling in very heavy rain events defined as the heaviest 1% of all daily events from 1958 to 2010 for each region of the United States. Changes in the eastern half of the nation are statistically significant at the 0.05 or higher levels and over the Great Plains, at the 0.1 level. (Right) Percent increases in the amount falling in very heavy rain events defined as the heaviest 1% of all daily events from 1958 to 2011 in the summer season for each region of the CONUS. Changes over the north-central and north-eastern parts of the nation are statistically significant at the 0.01 and 0.05 levels, respectively; all other trends are insignificant.

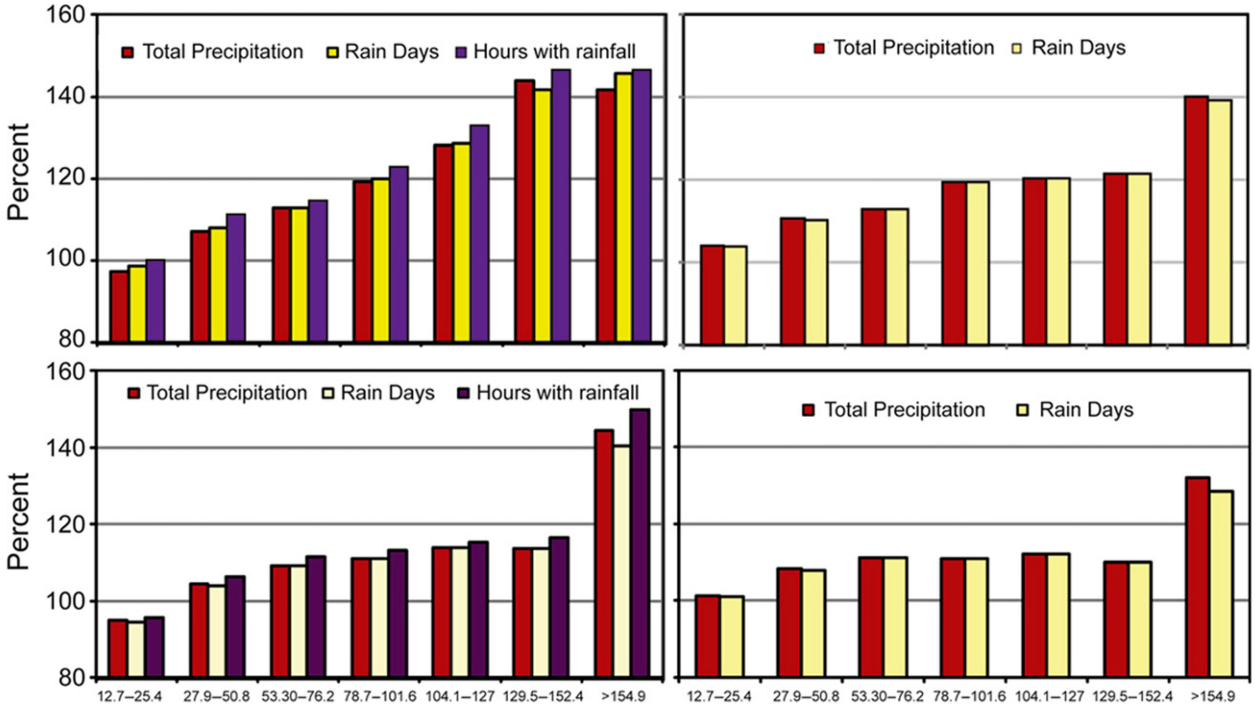

Figure 11 Comparison of intense precipitation days (upper line of plots) and multiday intense precipitation events (lower plots) over the central United States for 1979–2009 and 1948–78 periods sorted by day/event intensities (in mm). Estimates of precipitation characteristics for these 31-year periods were averaged and their ratios (in percent per station) are shown for HPD (left) and COOP (right) networks. Groisman, P. Ya., R. W. Knight, and T. R. Karl, 2012: Changes in intense precipitation over the central U.S. *J. Hydrometeorol.*, **13**, 47–66. [Available online at http://dx.doi.org/10.1175/JHM-D-11-039.1]

average 5 inches of rain) has been increasing in the past decades.

5.03.2.5 An Independent Near-Global Assessment of Changes in Intense Precipitation

Povl Frich (1999) developed a suite of indices that were proposed to be used as characteristics of climatic change. The pioneering idea beyond this proposal was a comprehensive suite of daily characteristics of temperature and precipitation that (together with the mean characteristics of climate) includes characteristics that can be used to describe anomalously high (low) climate conditions (extremes) and their changes. Among these characteristics were variables that are well suited to describe changes in intense precipitation. These characteristics do not describe 'extreme' rainfall as a very rare event (cf., as defined in Table 1) but instead these precipitation indices are flexible, easy to calculate, and their suite (with some reasonable modifications) can be used to describe heavy and very heavy

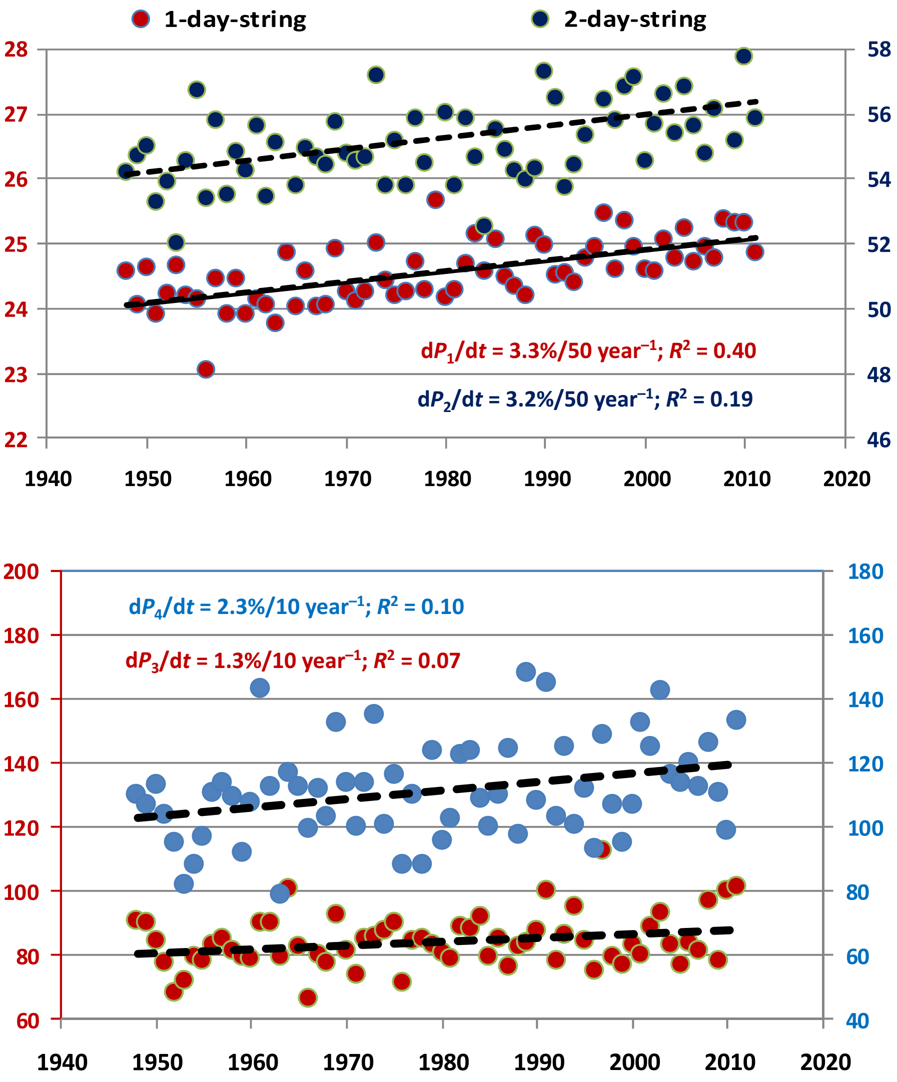

Figure 12 (Top panel) Mean intense precipitation, mm, per event that comes with 1- and 2-day-long events over the CONUS. The estimates are based on all intense events above 12.7 mm at ~6000 long-term US cooperative stations for the 1948–2011 period (Archive of Groisman et al. 2012). (Bottom panel) The same but for 3- and 4-day-long events over the midwestern United States.

precipitation across the world. These indices include the number of days with precipitation above 10 and 20 mm, annual daily maximum rainfall, maximum annual 5-day rainfall total, upper 95th and 99th percentile rainfall totals, and counts of daily events. These indices have been broadly used in regional and international assessments of intense precipitation change (cf., Frich et al. 2002; Alexander et al. 2006; You et al. 2008; Caesar et al. 2011; Easterling et al. 2003; Peterson et al. 2002; Aguillar et al. 2005, 2009; etc.). Below, we shall name them Frich indices. Frich indices were used in near-global and continental assessments of changes in the climate 'extremes' (cf., Frich et al. 2002; Klein Tank and Können 2003; Easterling et al. 2003; Moberg et al. 2006; Haylock et al. 2006; Alexander et al. 2006). The most comprehensive among these near-global assessments (Alexander et al. 2006; cf. Figure 4(c)) is described below.

For the 1951–2003 period, Alexander et al. (2006) reported near-global increase in the number of days with precipitation above 10 mm and in the contribution of the upper 5% of rain events to the annual totals. The pattern of the regions with increases in intense annual precipitation includes most of North America, regions surrounding (and including) the La Plata River Basin and Southern Brazil, most of Europe, and large areas in southern and eastern Asia. Analysis of the seasonal changes in the maximum 5-day precipitation totals (RX5day) shows a quite similar pattern as two other annual indices except the June, July, and August (JJA) season when the areas with decrease in RX5day became more spacious and include, for example, Western Europe, extratropical Far East, most of Australia, and Southern Africa.

For the 1901–2003 period, Alexander et al. (2006) repeated their trend analyses over a smaller part of the land (CONUS, southern Canada, Europe, Russia, and Australia) and found an overwhelming tendency of increase in annual characteristics of intense precipitation at the long-term stations in these regions. This coherent signal over most of the extratropics (if true) is spectacular but it also raises some concerns (cf., Figures 5 and 6) because (a) national practices in all of these countries 'improved' their precipitation networks many times during the past century in order to provide better measurements (which means more rain is reported by gauges); (b) the redistribution between frozen and liquid precipitation has been shifted with global warming, which also resulted in a better gauge catch (cf., Førland and Hanssen-Bauer 2000); and (c) in Australia, the number of rainfall totals accumulated during the weekend significantly increased after the national post office, where many rain gauges reside, ended its Saturday service (Groisman et al. 1999). It should be determined if and how these instrumental inhomogeneities affected statistics of intense rainfall in the data sets used by Alexander et al. (2006). Common wisdom hints that (except for the Australian 'post office' factor and the regions with cold season maximum precipitation) the impact of instrumental inhomogeneities on changes of annual daily maximum rainfall should be miniscule.

Figure 7 generalizes the results for the regions that were not initially covered in Groisman et al. (2005), as well as provides updates and new findings for the regions that were initially assessed in that work. **Table 4** provides a summary of these findings (except those that have already been described above). In these studies, time intervals assessed are different and different characteristics of heavy precipitation were considered, but everywhere these were the estimates of changes in heavy and (in some cases) very heavy precipitation according to the definitions of **Table 1**. Data analyses that focus on extreme rain events and their changes in the CONUS are further presented in the next subsection.

5.03.2.6 Changes in Extreme Precipitation over the Contiguous United States

Practically all results presented in the previous two subsections of 5.03.2 (except those in **Figures 3 and 11**) describe regional changes in heavy and very heavy precipitation events (according to classifications presented in **Table 1**). Changes in extreme precipitation are considered in fewer studies and are concentrated in the areas with dense networks of long-term precipitation time series. The CONUS is one of these such regions. Three different types of analyses were conducted here to catch the changes in extreme precipitation. Each type is presented in a number of publications and research reports, and below we assess a few of them that are representative of these analyses.

NOAA Atlas 14. Efforts to update NOAA Atlas No. 2 that contains precipitation frequencies of different intensity and duration have been conducted during the past 10 years (new NOAA Atlas 14; Bonnin et al. 2004–2012). The approach of this study is as follows: All precipitation events at each NOAA meteorological station in the United States (there are more than 25 000 such stations and, thus, the work is very arduous) are documented, their duration, total, and mean intensity (e.g., hourly, 6-hourly, daily, 2-, 7-, …, 45-day totals, etc.) are defined and their frequencies are estimated during the period of record and separately for the past three decades to check the differences with the previous NOAA Atlas (No. 2). Among the most important practical tasks of the Atlas creators were calculations of exceedance values of rainfall for different return periods (1, 5, 10, 25, 50, 100, up to 1000 years). For large return periods for most of the stations (for return periods of 100 years and above, for all), these calculations cannot be done without some assumptions. Generally, there were two of them: (1) it was assumed that extreme value distributions (Gumbel 1954; Generalized Extreme Value, (GEV) (Coles, 2001) and Pareto (Hardy 2010)) can be employed to approximate the upper tails of precipitation distribution of different duration (accumulated totals), and (2) that some regional features (shape) of the upper tail precipitation distribution are similar (regions were selected using L-moments method, cf., Hosking 1990; Hosking and Wallis 2005). After comparison of the exeedance dynamics for 2- and 5-year return periods (i.e., for very heavy precipitation events), Bonnin et al. (2011) concluded that their results broadly coincide with findings of Groisman et al. (2004, 2005): trends in exceedances at 1-day and multiday durations were statistically significant and increasing for the Ohio River Basin and surrounding states. They also found that for the Semiarid Southwest there are no significant trends in extreme precipitation during the post-World War II period. For larger return periods (25 years and above), the authors concluded that their data-driven approach cannot deliver statistically significant trend estimates (confidence intervals of these estimates were ±30%, while the absolute values of trends were on the order of magnitude less).

Extreme precipitation in two more regions of the western United States. **Figures 3 and 11** have already shown results delivered by a direct approach used by Groisman et al. (2012) in order to investigate intense precipitation (including extreme rain events) over southeastern and central regions of the CONUS. They deliberately simplify the area-averaging by analyzing the multidecadal total frequencies at all stations available at that period omitting to account for possible clusters (in any case the assessment based on fixed thresholds does not allow for accurate regional representation of extreme precipitation events frequency) and carefully accounting only for the average number of stations available during these periods in order to receive the accurate 'per station' estimates. The last liberty was also justified by the period used for analyses (1948–2009) that was initially rich with data from well-developed gauge networks. **Figure 13** shows similar estimates but for the northwestern (Washington, Oregon, and Idaho) and southwestern States (Four Corners: Utah, Colorado, Arizona, and New Mexico).

Climatology of intense precipitation distribution for these mostly dry regions is very different from that for the eastern United States (cf., **Table 1**) and is therefore shown separately in **Table 5**. **Table 5** shows that 79% of all intense precipitation events in the northwestern United States are delivered by days with moderately heavy precipitation (over the entire CONUS this mean number is close to 50%). Days with precipitation in the range from 1 to 3 inches comprise another 20% (defined for the eastern two-thirds as heavy rain events, but here the significant fraction of these events (those in the range from 2 to 3 inches) can be easily quantified as very heavy according to the 'percentile' scale presented in **Table 1**). Only one percent of intense rainfall is classified into the greater than 3-inch daily rainfall category. Frequencies of only these rain events have increased during the past three decades compared to the previous three decades (**Figure 13**). The probabilities of rare daily rain events (shown in **Table 5**), and the inverse values that are customarily interpreted as approximations of return periods

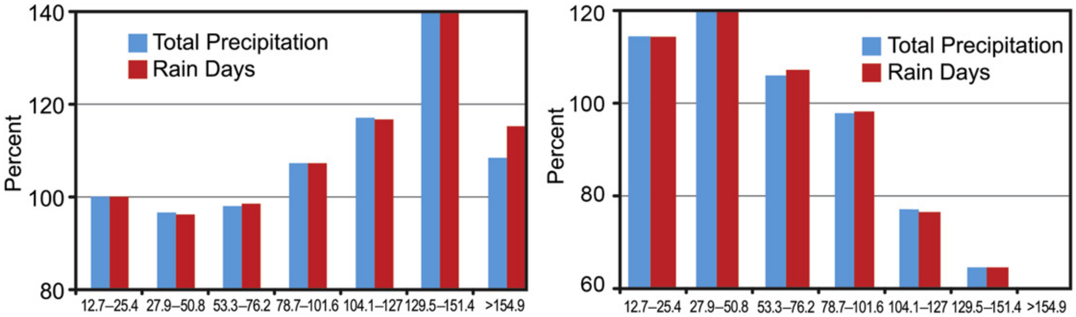

Figure 13 Same as in **Figure 11** but for daily precipitation events (COOP network) over the northwestern (Washington, Oregon, and Idaho; left) and southwestern (Four Corners: Utah, Colorado, Arizona, and New Mexico; right) United States.

(e.g., for events above 5 inches, this return period estimate looks like 100 years), should be interpreted with caution due to large spatial heterogeneity of precipitation pattern across the Northwest. Our estimates are averaged over 320 long-term stations of three states. Therefore, stations along the Pacific Coast and windward slopes of Cascades and Olympic Ranges reported most of regional extreme precipitation events, while the stations eastward of the coastal mountain ranges did not deliver many extreme rainfall events and participating in regional averaging reduced the probabilities of event occurrence shown in Table 5. When we selected the eastern boundary of the 'northwestern-most' United States by 121.5 °W (i.e., separating 126 stations in the wet coastal regions of the Oregon and Washington States), our counts of the very heavy and extreme daily precipitation events of 4 inches and above practically did not change, but their frequencies per year per station in the region increased to 0.091, 0.029, and 0.020 for events between 4 and 5, 5 and 6, and above 6 inches, respectively. Analysis of the results presented in Table 5 and Figure 13 provides an explanation of the peculiarity of the northwestern United States revealed in Figure 3. Only in the Northwest, Figure 3 showed a relative increase in the fraction of moderately heavy precipitation events compared to other intense rain events (above 25.4 mm). In fact, the frequency of the moderately heavy precipitation events (79% of all days with intense precipitation) did not change. The number of days with precipitation in the range from 1 to 3 inches decreased (another 20% of all days with intense precipitation) and this decrease predefined the sign of changes in the fraction of moderately heavy precipitation events within the intense rain events distribution. Changes in the upper one percent of intense rain events distribution were in a 'right direction' (increase, as in other regions of the eastern and central United States). However, their increase was insufficient to overweigh a decrease of the less intense but 20 times more numerous rain events (cf., Table 5 and Figure 13).

Southwestern United States (Four Corners States) is a dry region compared to all other parts of the CONUS. As a result, the scale of intense precipitation is shifted to lower ranges and on average the rain days with totals in the range of 12.7–25.4 mm occur here six times per year and comprise 86% of all days with intense precipitation. Another 12.5% of rain events come in the range from 1- to 2-inch day^{-1} and these events occur less than one per year (Table 5). Frequency of these events as well as the frequency of the two following ranges has increased in the past three decades compared to the previous period (Figure 13), while the frequency of rain days with daily totals above 4 inches decreased. It should be noted that whatever the spatial inhomogeneity across the region is (e.g., mountains against the lowlands and the low elevation biases of the GHCN-Daily sites used in our analysis), the total number of catastrophic rain events reported by 487 long-term stations in this region during the past 62 years was 97, 23, and 11 for 4 to 5, 5 to 6 and for rain events above 6-inch day^{-1}, respectively. These events (according to Figure 13) had occurred more frequently in the first three decades after World War II than thereafter.

5.03.2.7 Studies That Used a Parameterized Approach to Extreme Precipitation over the United States

DeGaetano (2009) analyzed the 30 maximum daily accumulation precipitation totals at the 1061 long-term high quality stations of the US Historical Climatology network during the

1950–2007 period. The analysis was conducted four times using 30-year running intervals, lengthening periods (30, 40, etc.) and for the starting dates of 1950 and 1960. At each site and for each period, he estimated the parameters of the GEV distribution (cf., Kharin and Zwiers 2005) that fit these maximums and assessed the changes in these parameters with time over the CONUS. Such analysis allows estimating the pattern of the return period precipitation amounts and their trends. His analysis revealed the regions where the changes in the GEV location parameter are significant (increase) and that (a) other GEV parameters did not change systematically with time and (b) there are regions (California, Intramontane regions, and Southeast) where no changes in extreme precipitation distribution were revealed. Areas where a significant increase in the return precipitation amounts was observed coincide with the areas shown in **Figure 10** (the northeastern quadrant of the CONUS) with an addition of the Pacific Northwest (coastal areas). After analysis with sub-division of the northwest into wet humid and dry parts with appropriate recalculation of the event frequencies (**Table 5**), this increase is also supported by estimates shown in **Figure 13**. It is important to note that the estimates provided by DeGaetano (2009) (precipitation amounts for 2-, 30-, and 100-year return intervals) directly address the concern of the civil engineering community. They are generally supported by independent estimates that do not rely upon any assumptions about the distribution of extreme precipitation, which strengthens the conclusions of this study and increases its practical importance.

Kunkel et al (2013) presented several metrics used to estimate extreme precipitation changes over the CONUS, including one based on time varying peaks over specified thresholds using statistical extreme value analysis (Tomassini and Jacob 2009; Cooley and Sain 2010; Maraun et al. 2009). For each year, the station-specific thresholds were set to the 97th percentile over days with at least 1 mm of rainfall (i.e., on average for the CONUS, at one to three rain events per year). Next, the exceedances of these thresholds were approximated with a dynamically changed generalized Pareto distribution, and possible changes during the 1948–2010 period in one of its parameters responsible for increase/decrease in 20-year return period values were tested at each long-term GHCN-daily station. This statistical analysis shows that about 76% of all CONUS stations experience increases in extreme precipitation, with 15% showing a statistically significant ($P < 0.05$) increase based on station-specific two-sided tests. A field significance test based on resampling entire years of data (to preserve spatial structure and within year seasonal patterns) was statistically significant ($P < 0.001$). Across the eastern two-thirds of the CONUS these exhibit a high degree of spatial coherence. Regions with greater numbers of stations with decreases are of smaller spatial extent and include the coastal northwest (cf., **Figure 13** for heavy precipitation). Moreover, when mapped, the results of this analysis indicate that everywhere across the CONUS extreme precipitation (20-year return period values) has increased during the past 62 years; however, not all of these changes can be claimed to be statistically significant. In particular, this type of analyses claims that over southern California and the Four Corners States the extreme precipitation has increased, while direct assessments of changes in extreme precipitation for California (Bonnin et al. 2011) and the Four Corners States (**Figure 13**) do not confirm this claim.

The above brief intercomparison of parameterized (distribution-based) and direct approaches shows that in the regions where a linearity of changes in heavy, very heavy, and extreme precipitation has occurred (the signs of changes are the same and only the rates of changes can be different), all approaches give noncontradictory similar results. However, when extreme distribution parameter estimates (fitting the distribution curves) are observed in the regions where nonlinear changes in intense precipitation have occurred (northwest, southwest, Mountains), the results based on this fitting (specifically our conclusions about changes in extreme precipitation based on this fitting and follow up extrapolations) may be compromised. For example,

- In the regions along the Pacific northwest coast, extreme rainfall has increased but analyses based on heavy rainfall in this region will generate opposite conclusions (cf., **Figure 13**, left panel and DeGaetano 2009 versus Kunkel et al. 2013).
- Extreme rainfall in the Four Corners States became much less frequent in the past three decades (**Figure 13**, right panel), but analyses based on heavy and very heavy rainfall in this region again generate opposite conclusions (Kunkel et al. 2013).

Finally, in the regions where different genera of extreme rainfall may occur (cf., Southeastern United States) their tendencies may well be different (Kunkel et al. 2012) and even have an opposite sign (cf., Southeastern United States, **Figure 2**).

5.03.2.8 Results Based on Daily Data versus Hourly Data

Precipitation is not a contiguous process and even in the days with extreme precipitation above 155 mm over the CONUS on average there are 9 h without rainfall (**Figure 14**). Therefore, assessments that use the daily time scale (daily totals) still can be considered incomplete answers to the questions about the precipitation dynamics especially during the warm season when rainfall immediately and in a multifaceted manner contributes to the surface water budget. As **Figure 14** shows for northern Eurasia, short-duration rainfall is most frequent in summer when its significant fraction comes in convective rainfall form (Sun et al. 2001). Unavailability of large long-term data sets with sub-daily time resolution has so far prevented global analyses of how the global change would manifest itself across the smaller time scales, specifically, at the hourly time scale during the warm season (i.e., for rainfall). The importance of this time scale is difficult to estimate because there is a large difference in impact on environment and/or the human-built infrastructure if, for example, a 25 mm day^{-1} rainfall total in fact occurred in an hour or less. The consequences for soil erosion (USSWCS 2003), flash flooding (Brooks and Stensrud 2000; especially in urbanized areas), and infrastructure damage (cf., Changnon and Westott 2002; Villarini et al. 2009) could be very different.

Changes in precipitation extremes under greenhouse warming are commonly assumed to be constrained by changes in the amounts of precipitable water in the atmosphere (Allen and Ingram 2002; Trenberth et al. 2003; Trenberth 2011; IPCC 2007). Global climate models generally predict only marginal changes

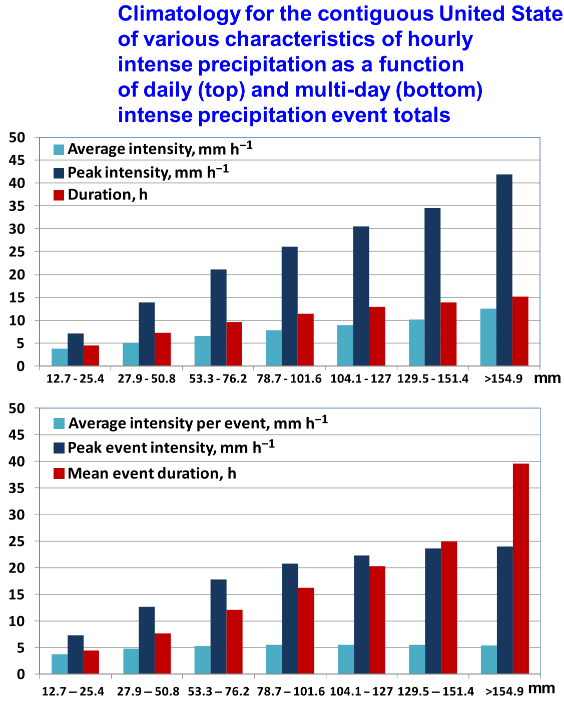

Figure 14 Precipitation duration in the extratropics estimated by recording gauges in northern Eurasia (Lebedev 1964) and the United States (archive of Groisman et al. 2012). Only intense daily events (>12.7 mm) are considered for the CONUS.

in relative humidity (Bony et al. 2006; Min et al. 2011), implying that the actual amount of atmospheric precipitable water is scaled with the water vapor content of saturation, which is governed by the Clausius–Clapeyron relation. The common belief is that the mean precipitation change is not obeying this relationship and the changes may be less than predicted (cf., Trenberth 2011). Indeed, changes in heavy ('extreme' in the language used by the modelers) daily precipitation in global climate models seem to be consistent with the 7% increase per degree of warming given by the Clausius–Clapeyron relation (IPCC 2007; Pall et al. 2007). In the absence of global analyses, we present below the recent findings accumulated in West Europe and the CONUS. In the former USSR (and currently in the Russian Federation), the dense network of the recording rain gauges exists and was used for climatological studies (e.g., Lebedev 1964), but has never been used for climate change studies.

Using the 99 years of hourly precipitation time series at de Bilt, the Netherlands, Lenderink and van Meijgaard (2008) tested how the mean daily and maximum hourly rainfall intensity are changing with the surface air temperature variations. They concluded that when the daily mean temperature exceeded 12 °C, hourly precipitation extremes increased with an increase in temperature twice as fast as expected from the Clausius–Clapeyron relation. Furthermore, analyzing the regional climate model output for central Europe, they found that this increase with summer surface air temperature in 1 hour precipitation extremes typically exceeds 10% K^{-1}, and in a large area even 15% K^{-1}, while daily extremes typically increase by 5–10% per degree (i.e., in line with the Clausius–Clapeyron relation).

In the previous subsection we describe analyses of extreme precipitation changes over the CONUS with time conducted by Groisman et al. (2012). Here, we describe a byproduct of this study when the same comparison between the last three decades and the previous three decades (and numerous other possible partitions in two equal groups of years) was conducted to assess the possible changes in the internal precipitation structure, such as mean and maximum hourly precipitation rates and precipitation duration (in hours). It was found that the climatology of these characteristics is systematically changing with increase of the rainfall range (cf., Figure 14). However, within each preselected range of daily or event totals, Groisman et al. (2012) found that mean and maximum hourly intensity and duration of precipitation daily and multiday events do not noticeably change. This conclusion remained valid with all partitions (by time, by season, or by any other external factor that we employed) and for each of the nine large regions of the CONUS shown in Figure 4(b). In Figure 15, we present one of these comparisons made several years ago (thus, no data after 2007 were used) for the eastern half of the CONUS east of the Mississippi River.

Results shown in Figures 11 and 15 hint that while very heavy and extreme rain days and events became more frequent with time, the processes that control the internal structure of these events, e.g., peak hour rain intensity and its duration, do not change. Eventually, in the regions with increasing frequency of extreme rainfall, the frequency of higher peak rain intensity will be observed but this will occur 'orderly' following the appropriate changes in daily rainfall intensities. The above conclusion is based on the various analyses for diverse regions and seasons but only for the conterminous United States. Thus, it can well be that in the tropics or in the polar regions, it will not be valid or, at least, the future users of

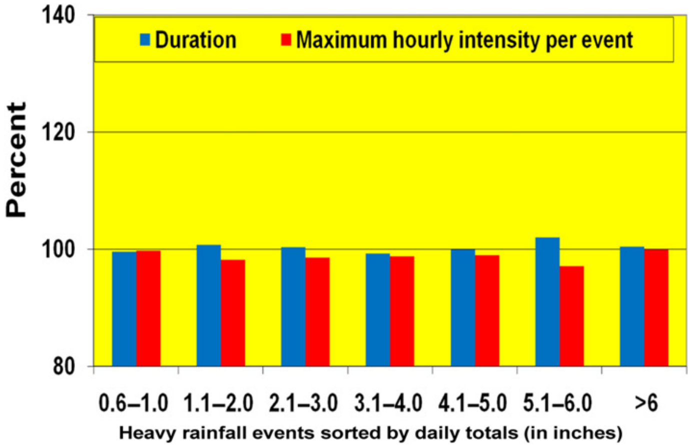

Figure 15 Comparison of heavy rainfall characteristics in the 'warm' and 'cold' Northern Hemisphere years in the eastern half of the CONUS (east of the Mississippi River). Data of 1715 hourly precipitation (HPD) stations for the 1948–2007 period were used in this comparison. Warm and cold years' rainfall records were scaled to the same number of stations available in both 30-year-long periods with the difference in the mean annual surface air temperature, ΔTNH, equal to 0.54 °C. Heavy daily rainfall events are sorted by the rainfall totals in the same manner as in **Figures 2 and 11** but the *x*-axes is in inches.

these results need a leap of faith to assume such development without testing it.

5.03.2.9 Prolonged No-Rain Periods

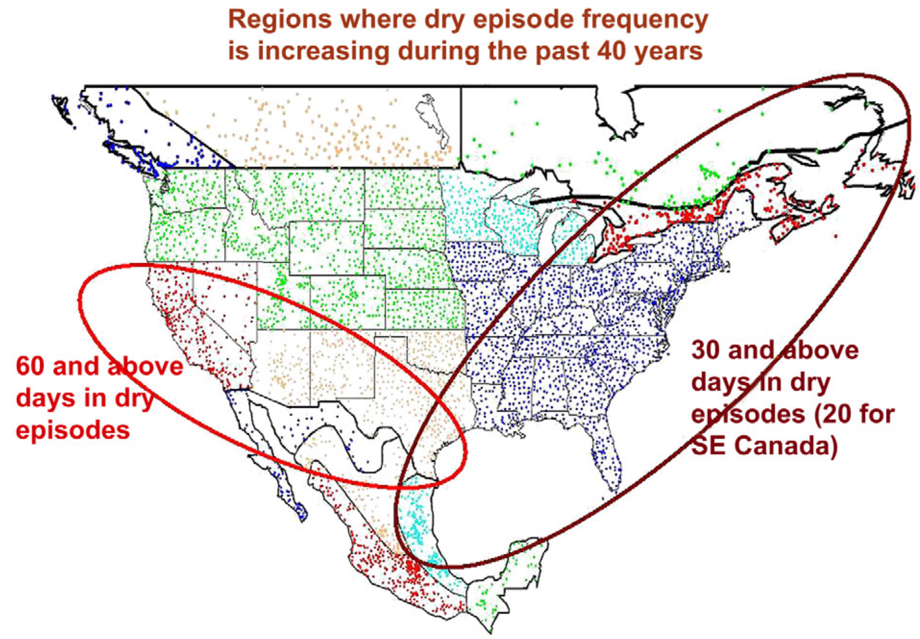
Karl and Knight (1998) and subsequent studies (Easterling et al. 2000; Stone et al. 2000; Groisman et al. 2004, 2005) all show that most of the precipitation increase over the United States, Mexico, and Canada occurs due to an increase in the frequency of intense precipitation while the frequency of days with average and light precipitation does not change or decreases. The tendencies, which emerged during the past 35–40 years with a disproportional increase in precipitation coming from intense rain events (Groisman et al. 2004, 2005), should lead to breaks in the parallel increase/decrease of both total precipitation and precipitation frequency. For the United States, this break was first reported in the mid-1970s by Sun and Groisman (2004) and for the northeastern quadrant of the conterminous United States was *projected* by Semenov and Bengtsson (2002), and thereafter confirmed by Groisman et al. (2005). Specifically, for the northeastern quadrant of the United States, the last authors reported an increase (or no change) in precipitation totals but a decrease in the number of days with precipitation. If continued, this decrease in precipitation frequency may lead to an increase in the frequency of another potentially dangerous type of extreme events: prolonged periods without precipitation (even when the mean seasonal rainfall totals increase). Groisman and Knight (2007, 2008) investigated whether this unfortunate development is already occurring in the warm season during the past several decades over North America south of 55°N, for the same period when we begin observing changes in frequency of intense precipitation events (i.e., since *c.*, 1970). North of 55°N, the station network density is generally insufficient for analyses used below. But, indirect evidence, first of all, an increase in areas consumed by forest fires in northwestern Canada (Gillett et al. 2004) and Alaska (Groisman et al. 2007), suggests a similar development in the northwest of North America.

The most detailed description of the approach they used and results are provided in Groisman and Knight (2008) for conterminous United States. However, the same analyses had been simultaneously conducted for Canada, Mexico, and Russia. In Russia, the analyses were conducted only for the regions south of 60°N in the European part of the country and south of 55°N in the Asian Russia for the same reason as for North America (cf., the previous paragraph). The findings of this assessment are as follows:

Over a substantial part of the conterminous United States (specifically, over the Eastern United States and the southwestern quadrant of the CONUS) during the 1967–2006 period, the frequency of occurrence of 30- (Eastern United States) and 60-day-long and above (Southwest) no-rain periods substantially increased (by 1.1 and 4.3 % per 40 years, respectively). These increases should be compared with the average fraction of occurrence of these dry episodes (1.5 and 14%, respectively). This means that over the Eastern United States, the frequency of these episodes nearly doubled. For the Northwestern quadrant of the CONUS and the humid Great Lake Area (as well as for adjacent regions of western Canada south of 55°N), for any duration of the dry episodes considered, we did not find statistically significant trends at the 0.05 level (using two- or one-tailed *t*-tests) in the fraction of the warm season consumed by these episodes.

The observed changes in the occurrence of the prolonged no-rain periods are not restricted to the CONUS but are expanded to the adjacent areas of northern and eastern Mexico and southeastern Canada (Groisman and Knight 2007; Figure 16). Specifically,

- Over *northern Mexico*, changes in the duration (in percent of the warm season, which is practically the entire year there) of prolonged dry periods 60 or more days without rain has increased by 9.4% during the past 40 years and this increase has been statistically significant (the long-term mean frequency of such dry episode is 49%).



Regions where dry episode frequency is increasing during the past 40 years
60 and above days in dry episodes
30 and above days in dry episodes (20 for SE Canada)

Figure 16 Schematic summary of statistically significant results showing the increase of prolonged dry day episodes across North America during the 1967–2006 period. Dots show the station locations with daily rainfall and temperature data used in the analysis and the dot colors (and solid lines) outline the regional boundaries within which the authors evaluated regional estimates of no-rain periods (Groisman, P. Ya., and R. W. Knight, 2007: Prolonged dry episodes over North America: new tendencies emerging during the last 40 years. *Adv. Earth Sci.*, **22** (11), 1191–1207.).

- Over *the humid Gulf Coast of Mexico*, there was a statistically significant increase in the frequency of prolonged dry periods, 30 or more days without rain, by 7.3% per 40 years (the long-term mean frequency of such dry episode is 20%). The increase here was mostly defined by a group of dry years in the late 1990s. In 1998, the total duration of prolonged dry periods 30 or more days without rain in this part of Mexico was extremely large, being twofold higher than the average (40% of days annually against the average 20% of days annually). It is worthy to note that this was a year of an extraordinary strong El-Niño.
- Over *southeastern Canada*, where precipitation is quite frequent, during the post-World War II period, most of the stations have not seen 30-day intervals without precipitation. Therefore, we lowered the criterion for minimum length of dry episode duration for the region to 20 days. These dry episodes are infrequent occupying on average slightly more than 1% of the warm season (1.2%). Therefore, while a twofold increase in the frequency of dry episodes during the 1967–2005 period (by 1.1%/40 year) is statistically significant at the 0.05 level, practical significance of this change can be questioned.

Over southern Siberia and Russian Far East (Figure 17 left panel), the frequency of dry episodes above 30 days during the warm season is quite small. This frequency had doubled during the 1956–2005 period. While the duration of the warm season is short (from four to five months), the mid-summer insolation and maximum temperatures are high. The prolonged no-rain episodes, combined with a general decrease (or no change) in rainfall (cf., Figure 1, top panel), create a substantial water deficit, increase the forest fire danger (Groisman et al. 2007), and the increase in areas consumed annually by the actual forest fires (Conard et al. 2002; Korovin and Zukkert 2003; updated).

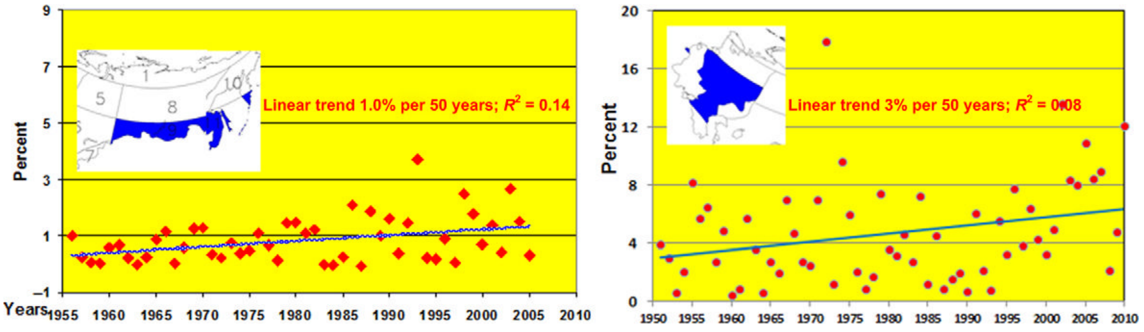


Figure 17 Dry episodes above 30 days during the warm season over (left) Asian Russia east of 85°E and south of 55°N and (right) European Russia south of 60°N. Both linear trends are statistically significant at the 0.05 level.

The European part of Russia south of 60°N (ER) spans from the taiga zone in the north to dry steppe and semi-deserts in the southeast. The growing season is 6 months on average and in the southern steppes can reach 8 months. The northern part of the region is considered a zone of steady agricultural production while in the south, in the region of the most fertile soils, droughts are frequent. Over this particular part of Russia during the past 60 years precipitation conditions noticeably improved: annual precipitation has increased (Bogdanova et al. 2010), natural runoff of the major river, Volga, has increased (Georgievsky et al. 2002), upper layer soil moisture during the warm season has increased (Speranskaya 2011), and the Palmer Drought Severity Index over the region has increased throughout the twentieth century (Dai et al. 2004). However, **Figure 17** (right panel) shows that during the same period of 'improvement' in the mean regional hydrological conditions, intraseasonal variability of rain events remained high and the frequency of prolonged periods without rain has increased. This signal was one of several that preceded a catastrophic drought in July–August 2010. There were drier summers over ER in the past (e.g., 1972 and 2002) than in 2010. However, in 2010, a strong water deficit due to a prolonged no-rain episode coincided with unprecedented very high surface air temperatures (in 2010, mean July–August surface air temperature over ER was 2 °C higher than in the previous record in 1972 and more than 5 °C above climatological mean values). In many locations across European Russia, absolute temperature records were exceeded and dramatic thresholds such as 'hot nights' were first reported as far north as at 60°N in St. Petersburg. This combination of a prolonged no-rain period and high summer temperatures decimated crops and caused numerous forest and steppe fires that in some cases spread toward settlements causing property and human life losses (Mokhov 2011). Smog over Moscow affected health of millions citizens and indirectly caused premature deaths (estimated to be of the order of 50 000). Extremely hot nights are harmful for human health when (according to Kalkstein and Davis 1989) the temperature conditions throughout the entire night even into the early morning do not drop below 25.9 °C (75 °F). They are closely correlated to the increase of detrimental health conditions (heart attacks, strokes, and, when combined with air pollution, asthma strikes). Over ER, such nights are very infrequent (**Figure 18**). Therefore, nearly all private houses and apartment buildings are not equipped with air conditioning. However, *10 years prior to the heat spell of 2010, the number of such nights nearly quadrupled*. This change was left unnoticed. Lessons were learned by Western Europeans who paid dearly during the heat spell of 2003, making them much better prepared for the next heat spell of 2006. However, a similar scenario was not expected to be relevant for the colder climate of ER and no preparations were made. Therefore, when the 2010 hot spell hit the cities in central ER (including the national capital), the losses, including human life losses were significant.

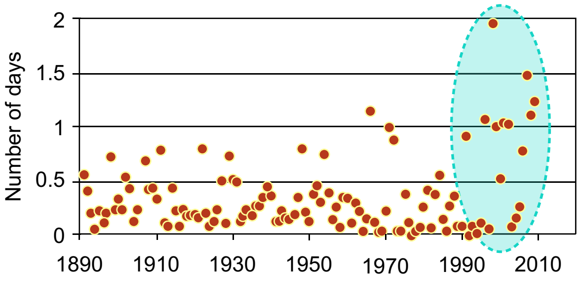

Figure 18 Number of days with 'hot' nights (when minimum daily surface air temperatures remain above 23.9 °C) area-averaged over ER south of 60°N during the 1891–2009 period. This number for 2010 exceeds five. These days closely correlate with an increased mortality of unprotected population.

Such weather conditions were absent during the period of instrumental records and extremely rare during the past millennium. However, for example, all weather anomalies described in old Russian Yearbooks ('Letopisi') for 1092 were repeated in 2010.

During the past 50 years, an increase in precipitation and soil moisture over ER was observed, but mostly overlooked were the concurrent changes that at the same time: (a) changes in the extratropical atmospheric circulation became more favorable to the blocking conditions over northern Eurasia (Mokhov 2011), (b) earlier spring onsets and winter thaws have gradually made a larger fraction of water resources accumulated in the previous seasons unavailable for the next summer season (Bulygina et al. 2011; Groisman et al. 2011), (c) areas affected by agricultural droughts were increasing (Meshcherskaya et al. 2011), (d) frequency of occurrence of prolonged ($\geq$30 days) no-rain periods was increasing (**Figure 17**), and (e) the number of days with 'very hot' nights with minimum temperatures $\geq$23.9 °C became disproportionally large in the past decade. Of course, nobody could predict the size and timing for the weather anomaly over ER in 2010 using climate change considerations. However, the ongoing climatic changes (including the severe heat wave outbreaks in Western Europe) staged the scene for it over ER and increased its probability.

5.03.3 Conclusions and Recommendations

In this chapter we investigated the current state of knowledge about the contemporary changes (mostly during the post-World War II period) of intense precipitation over the global land areas. It looks like these changes in the extratropical land areas were expected from theoretical considerations and their general features have already been reproduced (and projected into the future) by the most advanced contemporary global climate models (Meehl et al. 2007). However, details of these projections differ from model to model and it is not clear what will happen at the boundaries of the regions where these models hint to an increase in both intense precipitation and 'drier' conditions. Observations suggest that the area of such regions is significant over the mid-latitudes of the northern extratropics and includes a large fraction of the conterminous United States (cf., **Figures 10, 11, and 16**; Groisman and Knight 2008), southern Europe and Mediterranean (IPCC 2007; Zolina et al. 2012; **Table 4**), and a large swath of the northern Eurasia forest-steppe and taiga areas (cf., **Figures 1**, **Table 2**, and **Figure 17**; Groisman et al. 2009). How the changing structure of the hydrological cycle in these areas will manifest itself, affect the environment, and human well-being is an area of active current studies. In these studies, empirical assessments monitoring and trend analyses play an important role. They allow confirmation of theoretical considerations quantifying and refining them and deliver the knowledge about the here and now of the present state of the regional hydrological cycle and its dynamics.

A serious impediment for the studies of long-term changes in intense precipitation is a deficiency of comprehensive data sets of homogeneous time series from dense national meteorological networks available for international use. In the regions where such networks do not exist, we cannot complain because it takes time and resources for their establishment, and decades before they become useful for climate change assessments. But restricted access to the national network data in the regions, where these networks do exist, hampers reliable judgments about the most dangerous component of intense precipitation changes, the changes in the frequency and intensity of damaging extreme rain events. For example, the national precipitation network of Germany consists of more than 6000 stations (cf., Tomassini and Jacob 2009; Zolina et al. 2012), while the international (both European and global) archives have only 130 stations. Compared to two stations from Poland and one station from the Czech Republic, this is a good sample, but any study of rare extreme convective thunderstorms over these countries will be hampered by a danger of delivery of results that are nonrepresentative for central Europe. It does not help that the Global Precipitation Climatology Center (http://gpcc.dwd.de; Rudolf et al. 2011) most probably has this information (or an access to it) because the Center charter restricts dissemination of the station data to the international science community. The consequences of this impediment are (a) the focus of this chapter on the regions where we have unrestricted access to precipitation data and (b) an inability of the international scientific community to contribute to assessment of intense precipitation changes in the regions where these changes have occurred, were dramatic, and seriously affected the society. These regions appear on the screen only when something horrible happens (e.g., 2010 flooding in Pakistan). It would be much better if the analyses of intense precipitation changes and their possible consequences were made prior to such events. '*Informed means armed*'.

Final Notes. A few precautions advised to the researchers of intense precipitation changes were presented throughout the chapter. They include:

- There is a relationship between the network density at hand and the upper percentile (absolute rainfall) values whose changes the researcher can access (cf., the discussion on this matter in Groisman et al. (2005, 2012)). Both aspects are important. For example, scientists who declare the absence of heavy precipitation changes over the United States using 200 stations (instead of 6000 long-term stations) that are representative for less than 5% of the CONUS territory are not dissenters or skeptics but simply did not prepare well for their study.
- Light precipitation events are not consistently documented with time in many countries (**Figure 6**; Groisman et al. 1999). Precautions must be taken to avoid their impact on the artificial changes in the frequency of heavy precipitation. This precaution is especially important for high latitudinal countries (Canada, Russia, and Fennoscandia).
- Up to present, most (nearly all) observational results *and* the GCMs projections conveyed the information about changes in the frequency of heavy (sometimes very heavy) precipitation events. This is true even when nearly all climate modelers liberally use the term 'extreme' in description of their results. The *request* of the hydrologic and civil engineering communities to advise about changes in frequency and intensity of the actual extreme events (that cause real infrastructure damage and harm to human life) is not yet addressed to satisfaction and is an area of active ongoing studies. Those of these studies that focus on monitoring and documenting changes (i.e., based on observational data analyses) have a chance to succeed only in the regions with dense networks of long-term meteorological stations available to the national and international scientific communities (cf., achievements described above for the CONUS in Sections 5.03.2.4.6, 5.03.2.6, and 5.03.2.7). Of course, there are other approaches that can be used to address the request of this group of users that include regional high-resolution climate modeling and paleoclimatic and physical boundary considerations. These approaches, however, are beyond the focus of this chapter.

Summarizing, we conclude that over most of the extratropical land areas in the post-World War II period, increases in the frequency of heavy and very heavy precipitation events have occurred (**Figure 7** through 12, **Table 4**, Sections 5.03.2.3, 5.03.2.4, 5.03.2.5, 5.03.2.6, and 5.03.2.7). Over a sizeable part of mid-latitudes at the same time the frequency of the prolonged no-rain periods during the warm period has increased too (**Figures 16 and 17**; Zolina et al. 2012). Finally, for the regions with a dense network of long-term precipitation time series, observations support one of the major conclusions of climate modelers (Meehl et al. 2007; Trenberth 2011) about a general increase of precipitation intensity (cf., **Figure 19**).

In attempts to project prolonged extreme events (such as droughts and floods) in a given season, climatologists used to look for their precursors in the Earth system 'memory' that include anomalies in sea ice (SI) and snow cover extents (SCE), sea surface temperature (SST), and soil moisture and for their patterns (e.g., Southern Oscillation). However the major 'memory' component of the Earth system is the Earth Climate System itself. It began changing (IPCC 2007) and is not anymore a constant factor: SST, SI, and SCE anomalies of the past now became 'climatology' and it is time to include this new reality in our analyses of the frequency and intensity of extreme events. Apparently, when looking for extreme events occurrence one has to carefully select climatological variables that can be considered as precursors of these events and the changes in mean surface air temperature and precipitation may not be the best among them. Moreover, the characteristics of extreme precipitation and streamflow events that are commonly used in some segments of the scientific community, such as maximum annual precipitation (streamflow) values, are not an optimal choice and, in fact, may be misleading in the areas where increases in precipitation intensity and prolonged no-rain intervals simultaneously occur. Most of the CONUS is one of these such regions (cf., **Figures 10, 12, 16, and 19**, top panel).

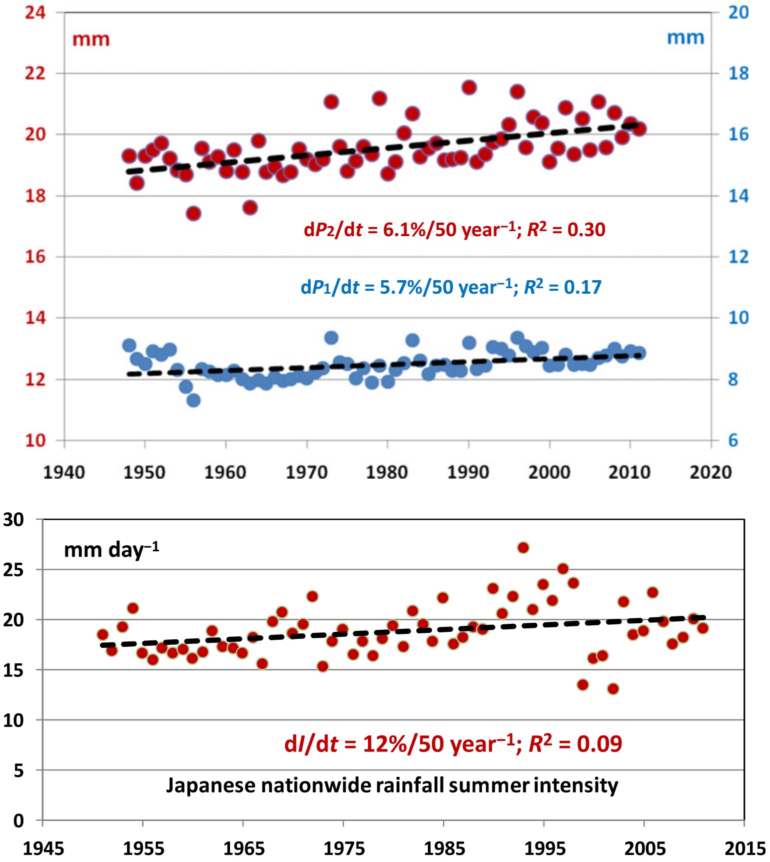

Figure 19 (Top) Mean daily precipitation, mm, per event that comes with 1- and 2-day-long events over the CONUS. The estimates of precipitation intensity in 1-day-long (P1, mm day^{-1}) and 2-day-long (P2, mm (2 days)$^{-1}$) are based on all precipitation events above 0.5 mm at ~6000 long-term US cooperative stations during the 1948–2011 period (updated archive of Groisman et al. 2012). P1 and P2 were selected to be nonoverlapping events (1-day events are not included in the 2-day events) and together contribute approximately 60% of nation precipitation totals. (Bottom) Mean summer (JJA) rainfall intensity, mm day^{-1} over Japan. Estimates of the annual precipitation intensity over the country also show an increase (with the mean rate of 14% 50 year^{-1}) but are not presented here due to our concerns about the instrumental homogeneity of the cold season precipitation measurements in this country after introduction of automation (tipping bucket rain gauges) in the early 1970s and thereafter.

5.04.1 Introduction

Almost 25% of the world's population lives in tropical mountainous regions, and about 60–70% of the world's population relies on mountains for freshwater needs ranging from drinking water to food production, ecosystem services, and industrial use (United Nations 2002 International Year of the Mountains, http://www.mountains2002.org). Onishi et al. (2007) report that 60% of the freshwater resources input to China's Yellow River originated from its headwaters, and Thurow et al. (1998) estimated that over a billion people depended directly on the sustainability of steep lands for their subsistence. About half of the world's freshwater resources come from mountains, and a significant fraction of the world's food production takes place in the alluvial plains at the foothills of major mountain regions (e.g., Garrido and Dinar 2008; Nellemann et al. 2009). Changes in precipitation regimes associated with land use/land cover changes and population pressure in the continental highlands of the tropics could lead to increased aridity of alpine environments, decrease in groundwater recharge, and runoff production, thus potentially altering the hydrological regimes of downstream regions including some of the world's major river basins (e.g., Ganges, Indus, and Amazon). Mountain ecosystems are controlled by complex temperature–moisture conditions in the lower troposphere and are especially vulnerable to hydroclimatic variability and change. Tropical montane forests (TMFs), and tropical montane cloud forests in particular (TMCFs; see Chapter 5.5), combine high biodiversity and endemic species, with the tropical Andes having Earth's highest biodiversity (Krajic 2004; Myers et al. 2000, among many others). With worldwide distribution and strong environmental and climatic gradients, mountains are elevated observatories where the impacts of climate variability and longer term change might be first detected (Kupfer and Cairns 1996; Still et al. 1999; Foster 2001). Upward migration of alpine plants and alpine tree lines that has been found in several parts of the world is most likely caused by local and/or regional temperature increases and water stress impacts, particularly rising cloud base levels, decreasing stratus clouds and fog, and consequently decreasing rainfall, especially light rainfall (e.g., Peñuelas and Boada 2003; Malanson and Cairns 1995). Changes in cloud base are implicated in large-scale changes in animal communities (e.g., Pounds et al. 1999; Thomas et al. 2004) and amphibian declines (e.g., Pounds and Crump 1994; Pounds et al. 2006). Paleoecological evidence shows that montane communities have responded dramatically to past climate and may face unprecedented challenges in the future (Bush and Silman 2004; Bush et al. 2004). Importantly, estimates of the effects of global climate change on biodiversity in montane systems are poorly constrained because of poor understanding of species and ecosystem responses to climate (Malcolm et al. 2006; Thomas et al. 2004). Furthermore, nonlinear interactions among precipitation, vegetation, and soils have a significant impact on erosion processes and sediment yield in mountainous regions, which in turn affect ecosystem stability (e.g., Whol et al. 2012; Roering et al. 2003; Inbar and Llerena 2000).

In the water resources literature, mountains are popularly referred to as nature's freshwater towers [http://www.banffmountainfestivals.com/summit/2003/themes/]. This conveys the idea that freshwater released and stored at high elevations is delivered to lowlands and downstream ecosystems much in the same way that man-made water towers drive potable water distribution systems. The imagery stems from the observed increase in rainfall with elevation upwind mountain crests, which can be explained to first order by the forced (enhanced) lifting (cooling) of moist air to the lifting condensation level (LCL) forming (orographic) clouds, which over time produce precipitation with a significant increase (orographic enhancement) relative to adjacent low-elevation areas (Figure 1). Large arid or semiarid plateaus and valleys lay on the leeside (relative to the regional climatology of moisture

http://dx.doi.org/10.1016/B978-0-12-384703-4.00504-9

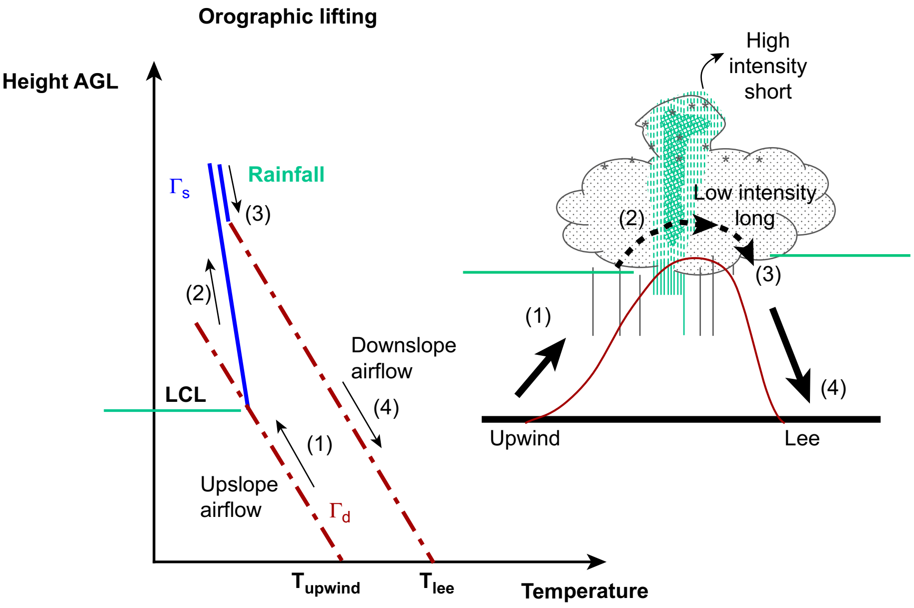

Figure 1 Conceptual representation of orographic precipitation processes. Colder and moist upwind air is forced to rise (1) until it reaches the lifting condensation level (LCL); it then becomes saturated, leading to the development of an orographic cloud, and with time, rainfall (2). As saturated air moves over the mountain (3), it eventually leaves the cloud and flows downslope on the leeside (4). If there is instability, localized convection can be triggered, leading to high-intensity precipitation. (T, temperature; Γ, lapse rate; subscript: d, dry adiabat; s, saturated adiabat).

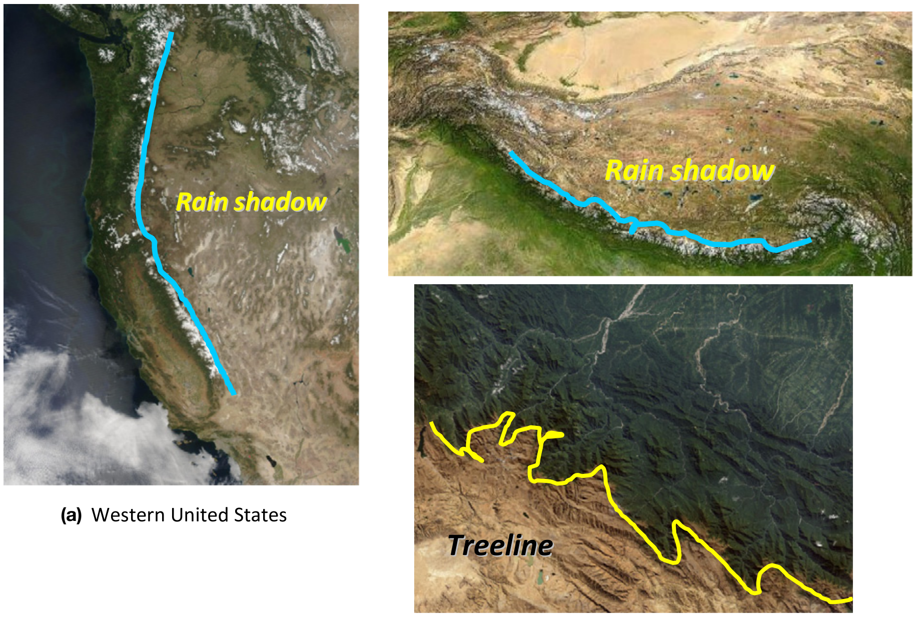
transport) of topographic divides downwind of major mountain barriers, such as the Andean and Tibetan Plateaus, and the Sierra Nevada mountains in California (e.g., the Death Valley) (e.g., Barros and Lettenmaier 1994). At very high elevations and low temperatures, the saturation vapor pressure in the atmosphere (sometimes referred to as the moisture-holding capacity of the atmosphere) is smaller, and consequently, even if clouds form the cloud droplet concentration is too small to produce precipitation. Thus, typically, there is an orographic precipitation maximum on the slopes at some distance upwind of the mountain crest (Figure 1). At low elevations, leeside rain shadows can be explained by drier (due to upwind depletion) and warmer air flowing downslope. Although this classical description of the spatial and altitudinal contrasts of precipitation across topographic features is consistent with the broad landscape-scale evidence of vegetation contrasts (Figure 2), quantifying orographic precipitation generally and quantifying it at the spatial and temporal scales that reflect governing key meteorological, hydrological, and ecological processes requires high spatial and temporal resolution observations and models that can capture the complexity of precipitation processes including the diurnal and seasonal cycles and interannual variability. One major challenge in assessing climate impacts and climate vulnerabilities at local places, and at the scales of headwater catchments in mountainous regions in particular, is the fact that Global Climate Model (GCM)-based predictions and integrated assessments such as those produced by the Intergovernmental Panel on Climate Change (IPCC) are available at very coarse spatial scales, and confidence in GCMs' ability to capture present climate processes at regional and smaller scales in the lower troposphere is very limited. For example, even in the case of reanalysis data sets obtained by optimal assimilation of model results and observations over the recent historical record (typically about 50–60 years), there is significant discrepancy between the statistics of extremes as compared to rainfall observations (e.g., Sun and Barros 2009). Nevertheless, these scenarios have been used to provide baseline information for constructing a subset of alternative vulnerability scenarios, which are then constrained locally (e.g., Bates et al. 2008; Vörösmarty et al. 2010).

Figure 3 shows the annual cycle of river discharge from mountain streamgauges randomly selected among headwater catchments of some of the world's largest river basins in the University of New Hampshire-Global Runoff Data Center Composite Runoff Fields Version 1.0 (http://www.grdc.sr.unh.edu). The two top panels illustrate the difference between two headwater catchments (of different sizes) on the eastern slopes of the Andes, although at different latitudes. The data on the left-hand panel shows only the signal of the South American monsoon (JFM, January, February, and March) for a tributary of the Parana river, whereas the right-hand panel shows also a strong signal in the Austral spring (OND, October, November, and December) for a tributary of the Amazon, reflecting the relative contribution of large-scale moisture transport (JFM) versus regional and local sources (OND) that can amount up to 30–35 mm in the annual cycle of precipitable water (Figure 4). Both regional and synoptic-scale moisture sources are susceptible to change if the regional climate warms. Rainfall intensity increases in December, January, and February (DJF) and decreases in June, July, and August (JJA) at both the Andes locations, along with significant increases in precipitation intensity and number of dry days (Bates et al. 2008). That is, the wet season would become wetter with more intense rainfall events, whereas the winter season would become very dry. This is consistent with regional drying of the lower troposphere as rainfall intensity in the winter is



(b) Himalaya and Tibetan Plateau

very low and is strongly controlled by local moisture sources and fog–stratus interactions. The bottom row in Figure 3 shows the annual cycle of streamflow for two stations in the northern hemisphere: one in the Snake River (left-hand side), a tributary of the Columbia river originating in the Rocky Mountain in North America, and a tributary of the Ganges in the southern slopes of the Himalayas in the Indian subcontinent (right-hand side). The streamflow of the former is dominated by snowmelt

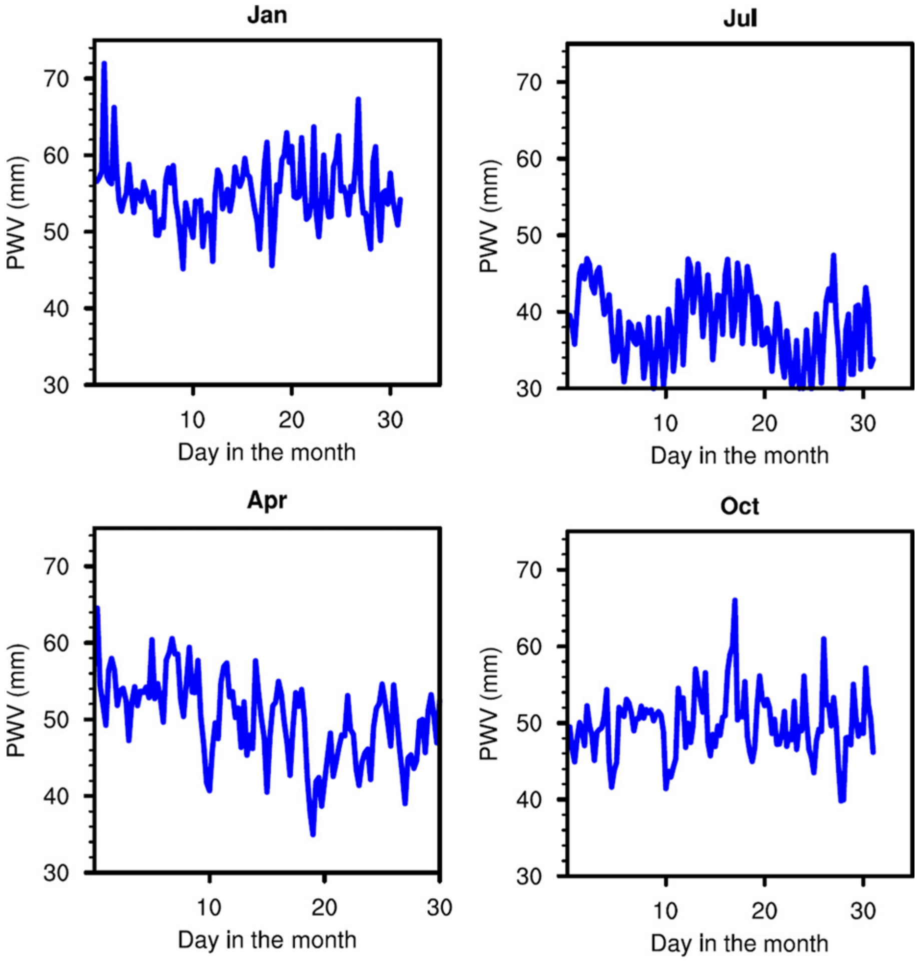

Figure 4 Day-to-day variability of precipitable water (PWV) from the ERA data set (European Center for Medium term Weather Forecasting (ECMWF) Reanalysis ERA) over the Kospiñata river valley in the Central Andes for four different months in 2011: January – wet season; July – dry season. Source: ERA-Interim data-portal.ecmwf.int/data/d/interim_daily.

runoff in the spring; the streamflow in the latter is dominated by summer monsoon runoff. For the Snake river basin, there is large uncertainty in simulated climate change projections; however, most model results suggest changes in timing of snowmelt (earlier in the year) and increases in evapotranspiration (ET) leading to lower soil moisture overall, and therefore a likely shift in the seasonality of the streamflow peak (Bates et al. 2008). In the case of the Indian monsoon, global model simulations of climatic change scenarios point to a significant increase (10–20%) in runoff associated with increased rainfall intensity during the monsoon (Bates et al. 2008). However, a significant increase in the number of dry days over the Indian subcontinent, and over the Gangetic Plains in particular, could counteract any benefits from increased infiltration and runoff production, leading to essentially no change in groundwater recharge regionally.

Large regional variability in the vulnerabilities of mountainous regions to climate coupled with differences in governing precipitation processes at different locations implies the need for climate vulnerability assessments and adaptation studies that are based on an understanding of the governing hydrometeorological processes at regional scales and provides an impetus to the case that development of long-term observing networks in mountainous regions is foundational for devising climate mitigation and adaptation strategies in mountainous regions. The idea that climatic observations are essential to address environmental change and sustainability questions is not new (e.g., Plummer et al. 2003). Yet, mountains remain generally among the least observed landscapes in the planet (e.g., Viviroli et al. 2011). For example, the first above-canopy, science-grade rainfall observing network in the eastern slopes of the Andes from the Amazon basin up to the top of Parque Nacional del Manu was installed only recently, in the Fall of 2011 (Figure 5). As opposed to what happens in the eastern slopes of the central Andes where rainfall peaks in the early afternoon, rainfall peaks in the evening and early morning in the south-facing slopes of the central Himalayas (Figures 5 and 6). On the one hand, daytime ET plays an important role in modulating soil moisture and consequently surface–subsurface interactions and groundwater recharge; on the other hand, moisture recycling by ET at the ridge-valley scale can provide the supply needed to explain the observed diurnal cycle of precipitation when the regional moisture flux is insufficient (Bushan and Barros 2007). We hypothesize that

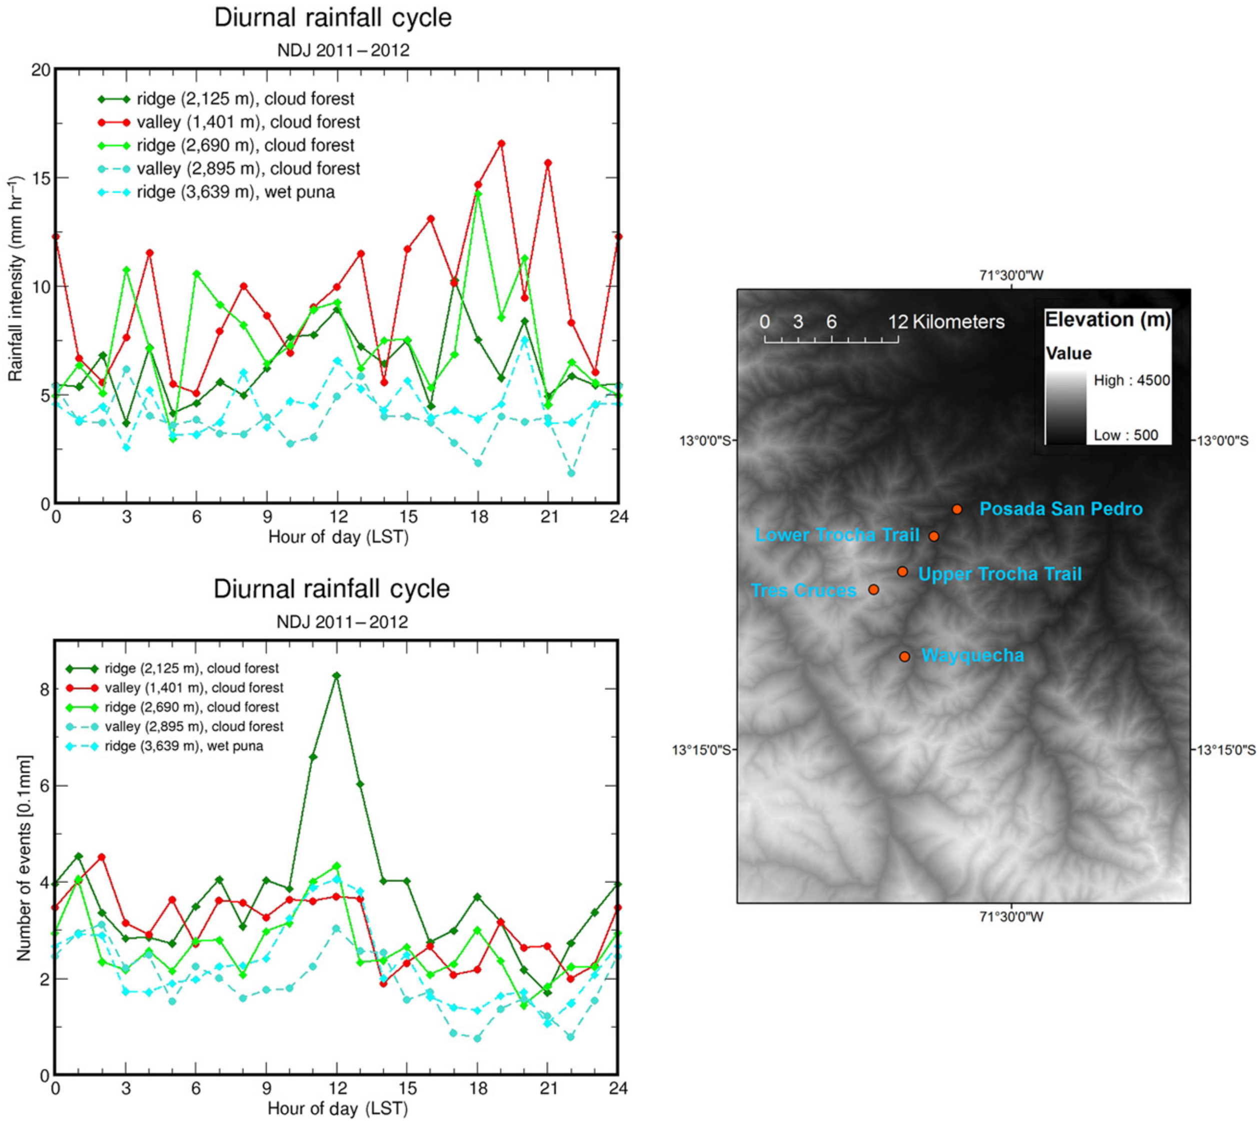

Figure 5 Characteristics of the diurnal cycle of rainfall at rain gauges in the Central Andes during the South American monsoon in 2011–12. Events are defined based on the daily average number of records of 0.1 mm h^{-1}. The diurnal cycle of rainfall intensity correspond to average values of recorded rainfall intensity at the specific time of day when rainfall occurred.

daytime ET in the central Andes is important to provide moisture supply for midafternoon upslope dense fog and low stratus that produce light rainfall at valley headwaters, whereas in the Himalayas it provides the moisture supply for afternoon cumulus convective activity (see further discussion in Section 504.01.2).

Published estimates of the contribution of orographic precipitation to global freshwater resource stocks vary from values greater than 70% in the snow-dominated hydrologic regimes of the western United States (e.g., Bales et al. 2006) to 25% in humid climates and 45–50% in arid and semiarid regions (Viviroli et al. 2011). However, even in regions where mountain freshwater per se is not essential for the sustainability of adjacent lowlands, precipitation patterns and associated runoff generation and erosion processes are critical in landscape evolution and in sustaining the incoming material fluxes (sediment, debris, and nutrients) that are essential for the sustainability of floodplains and river systems at low elevations (e.g., the eastern Andes and the Amazon basin, McLain and Neiman 2008).

5.04.2 Landform and Orographic Precipitation Regimes

Classical measurements of precipitation date back centuries and consist of cumulative rainfall amounts (direct observations) over predetermined durations (e.g., 1 day, 1 month) at point locations. Remote and difficult access severely increases the costs of installation and maintenance of precipitation networks in mountainous regions. A fundamental shift in the measurement paradigm took place with the advent of the

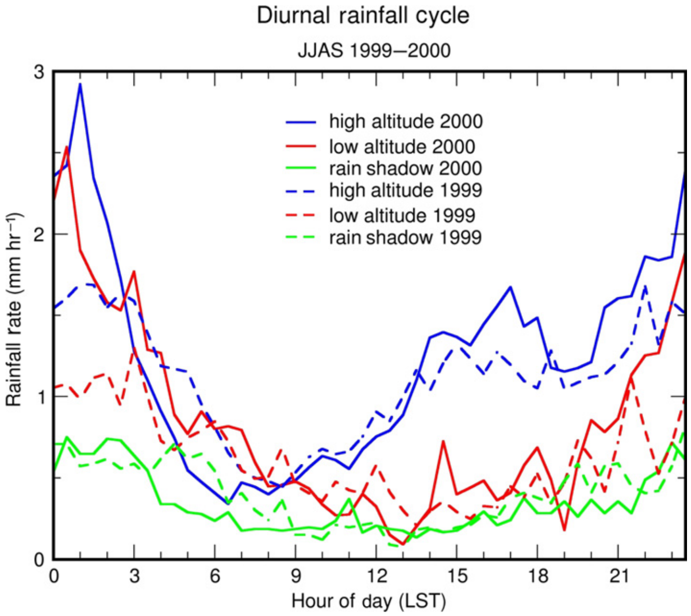

Figure 6 Diurnal cycle of monsoon rainfall in the Central Himalayas at high (ridges) altitude and low altitude (valleys) and rain shadow locations in the Marsyangdi river valley in 1999 and 2000. The rainfall rate is calculated including also times when it was not raining; it is not a rainfall intensity. Adapted from Lang and Barros 2002; Barros et al. 2000.

satellite era in 1978 and the launch of the first microwave and infrared imagers, the popularization of ground-based radars in the late 1980s and 1990s, and finally the Tropical Rainfall Measurement Mission (TRMM) satellite with the first precipitation radar in space; that is, clouds and precipitation fields can now be mapped globally at increasingly high spatial and temporal resolution over time (Adler et al. 2000; Negri et al. 2002, 1994 among others; see Chapter 5.9 on rain measuring satellites). The panoramic view of clouds and precipitation systems afforded by remote sensing reveals the complex spatial gradients of transient cloud and rainfall fields, the nonlinear and often apparently chaotic evolution of storm systems on the one hand, and the remarkable space–time organization imposed by landform on the same fields on the other hand. However, experience has demonstrated that until science-grade observing systems are put in place, precipitation in mountainous regions tends to be underestimated based on operational ground-based networks and satellite data by as much as 300% and higher (e.g., Barros et al. 2000), and the characteristics of rainfall (seasonal and diurnal cycles, duration and intensity of specific events) and spatial gradients that in turn strongly determine its availability as a resource are poorly described (Figure 7).

5.04.2.1 Rainfall

Precipitation in continental monsoon climates in the tropics is characterized by strong annual cycles, with most of the precipitation falling during the warm season: JJA in the northern hemisphere and DJF in the southern hemisphere. From onset to demise of the monsoon, large-scale atmospheric circulations sustain the bulk influx of moisture to mountainous regions. However, the physical processes by which the complex spatial and temporal patterns of precipitation observed from the ridge-valley scale to the mountain-range scale unfold are poorly understood. In the past 10 years, analysis of space-borne observations of clouds and precipitation systems revealed unique features in the spatial organization of rainfall and cloudiness in mountains (the Himalayas and the Andes in particular) that suggest strong landform controls on precipitation processes (Garreaud 1999; Garreaud and Wallace 1997; Barros et al. 2004 among others). Specifically, analysis of TRMM PR (Precipitation Radar) and infrared imagery data along the Himalayas suggests orographic precipitation processes that include cells of localized shallow convection embedded in bands of stratiform rainfall from the foothills up to 5000 m (Lang and Barros 2002; Barros et al. 2004). For example, Barros et al. (2004) and Giovannettone and Barros (2008, 2009) showed that the first principal component of cloudiness in the Himalayas and the Andes explained 50–70% of all variability (Figure 8), and they also showed space–time persistence on the distribution of precipitation features (Figure 9). This clear and strong modulation of clouds and precipitation fields by mountains viewed from space can be explained by their strong 3D complex morphology, which at a regional scale performs like an obstacle to synoptic-scale flow and as an elevated heat source with a diurnal cycle governed by solar forcing. At the ridge-valley scale and across topographic barriers modulation of flows by topography, spatial organization of convective activity, and diurnal mountain-plain and ridge-valley circulations organize aerosol distributions, which play an important role as cloud condensation nuclei (CCN), clouds, and ultimately precipitation processes (e.g., Shrestha and Barros 2010; Brun et al. 2011).

Figure 10 summarizes various habits of orographic clouds and precipitation including (1) rainfall associated with large-scale weather systems: stratiform rainfall associated with large-scale weather; stratiform rainfall with shallow embedded

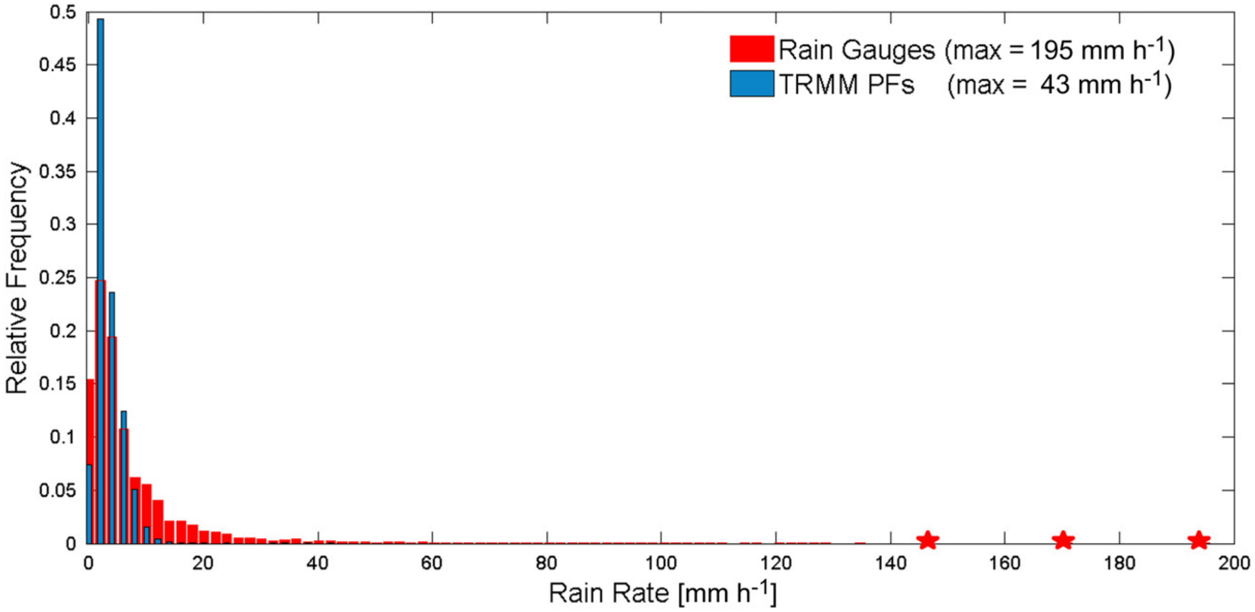

Figure 7 Intercomparison of the histograms of rainfall rates (resolution is 2 mm h^{-1}) based on 12 years of TRMM precipitation features in a region centered over the Kospiñata valley and recent observations ($<$1 year) from five rain gauges. Three highest observed rainfall intensities are marked with red stars. Although the period of record is very different, the objective of this figure is to illustrate the differences in the range of observed rainfall. The histograms show that the satellite misses light rainfall ($\leq$2 mm h^{-1}) and underestimates higher rainfall intensities. Precipitation features courtesy of Chuntao Liu. Precipitation features climatology after Liu et al. 2008.

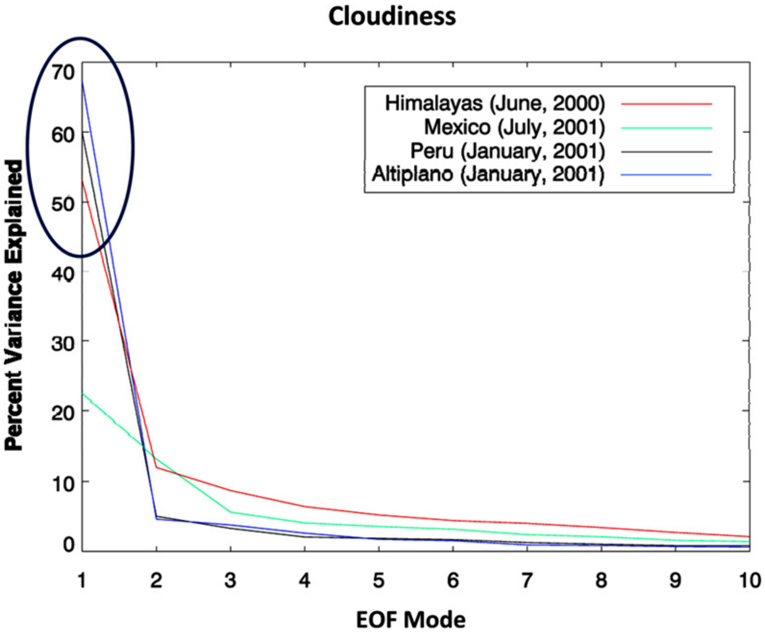

Figure 8 Empirical orthogonal function (EOF) analysis of infrared brightness temperature as an indicator of cloudiness over the Himalayan range, the Sierra Madre Cordillera in Mexico, the Central Andes in Peru, and the Altiplano region in the Andes. Adapted from Giovannettonne and Barros (2009).

convection, which dominates the occurrence of heavy localized nocturnal rainfall in the Andes and the Himalayas; and stratiform rainfall with embedded deep convection associated with the propagation of mesoscale convective systems such as in the warm season in the Southern Appalachians and (2) rainfall associated with the interaction between large-scale weather and local circulations: rainfall resulting from feeder–seeder interactions between stratiform clouds and low-level orographic clouds during midday and between low-level clouds and fog (advection fog in the morning, upslope fog in the late

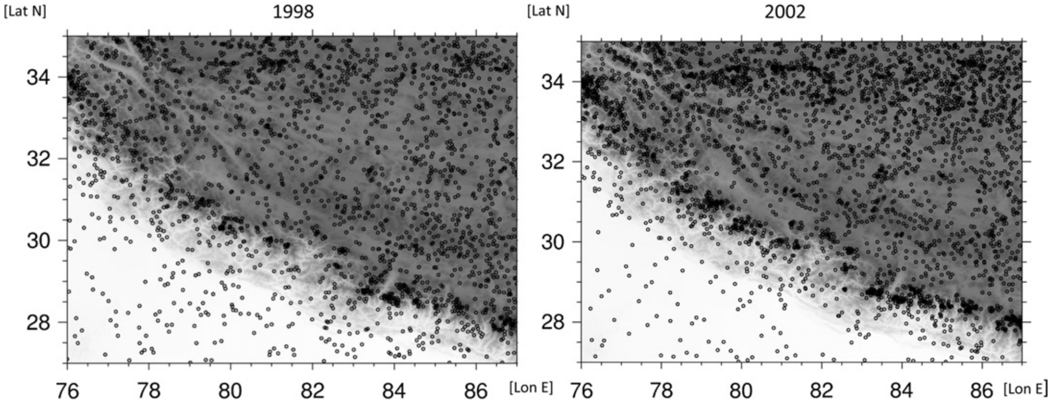

Figure 9 Examples of interannual persistence of TRMM warm rainfall features (Nesbitt and Zipser 2003) locked to ridges along the Himalayan range and high elevation features in the Tibetan Plateau. Adapted from Barros et al. (2004).

afternoon, and radiation fog in the early evening), shallow cumulus convection associated with local ridge-valley circulations, and isolated deep convection associated with thunderstorms (evening, midnight, and early morning). For further in-depth discussion of the dynamics of orographic precipitation systems see Houze (2003, 2012). Note that consequent to the 3D space–time organization of clouds and precipitation, there is a corresponding spatial and temporal organization of air and land surface temperature, net radiation, soil moisture, boundary layer relative humidity, and ET, that is, the conjugated water and energy budgets.

At a macroscale level, some fundamental differences in rainfall relate to seasonal climatic variations (e.g., monsoon systems), diurnal cycle, rainfall intensity (light versus heavy – $>10\,\mathrm{mm\ h^{-1}}$), and rainfall duration (typically, long for light rainfall and short for extreme rainfall). Previous research in the Himalayas, Central America, and the Central Andes using TRMM radar data (Giovannettone and Barros 2008, 2009; Barros et al. 2004) showed that orographic convective rainfall systems exhibit a strong diurnal cycle that is strongly organized by topography with deep and shallow ($<5\,\mathrm{km}$) convective systems aligned with ridges and elevated features during the daytime and moving downslope at night along the ridges of valleys opening to the adjacent plains (Figure 11). The diurnal cycle of rainfall in the central Himalayas exhibits afternoon and evening peaks with nocturnal maxima during the monsoon (Barros et al. 2000; Barros and Lang 2003). This late night/early morning rainfall maximum accounts for about one-third of the cumulative monsoon rainfall and causes regular flash floods in headwater streams everywhere along the Himalayan range.

One interesting feature of Andes' hydroclimatology is the alternation of wet and dry spells similar to active and break phases of the monsoon in the Himalayas (e.g., Nogues-Peagle et al. 1997; Chapter 5.14 deals with Andes snowpack). Previously, analysis of the diurnal cycle of convective rainfall in South America during the monsoon season (DJF), and specifically along the steep terrain in the eastern slopes of the Central Andes, also reported a strong diurnal cycle with an evening peak and nocturnal maxima along the foothills of interior valleys (Negri et al. 1994, 2002; Garreaud 1999, Garreaud and Wallace 1997; Yang and Slingo 2001; Mapes et al. 2003; Okumura et al. 2003; Nesbitt and Zipser 2003). However, recent observations from the Kospiñata river basin suggest that in contrast to the Himalayas, the evening rainfall peak occurs at lower elevations and in the valleys in the Andes (Figure 5). Heavy, localized nocturnal rainfall at lower elevations is the leading cause of powerful flash floods, causing myriad landslides and debris flows at elevations below 3000 m, illustrated by the sharp transitions in the hypsometric curves of these regions (e.g., Figure 12). Daytime rainfall on the ridges peaks in the early afternoon (noon–3 p.m. local standard time (LST)) followed by another rainfall peak in the evening, maintaining wetness of the soil during the rainy season and thus making it less stable.

A critical challenge to rainfall estimation from satellites is the detection of light rainfall. In addition, terrain effects in mountainous regions also play an important role in limiting the accuracy of precipitation estimates (Barros et al. 2000; Barros and Tao 2008; Prat and Barros 2010a,b). There is therefore a great need for ground-based observations in order to quantify total rainfall and to fully characterize the diurnal cycle. Persistent fog (drop size $<50\,\mu\mathrm{m}$; Eldridge 1961; Awan et al. 2011, among others) and light rainfall are not main features in the central Himalayas during the monsoon, whereas this is not the case in the Andes (Figure 5), Central America, Coastal Range of Southern California and Southern Appalachians, and Hawaii (e.g., Gomez-Peralta et al. 2008; Juvik and Nullet 1995). Indeed, recent multiyear observations in the Southern Appalachians suggest that relatively light rainfall dominates net annual precipitation. Figure 13 shows the fraction of rainfall that is contributed by light rainfall ($<3\,\mathrm{mm\ h^{-1}}$) in the Great Smoky Mountains in North Carolina, which varies between 30 and 40% for annual rainfall and goes up to 60% and higher in winter and spring. Interannual variability of rainfall is very large, with rainfall on the eastern slopes varying by as much 1 m of net precipitation between dry and wet years. Note that the threshold criterion of $3\,\mathrm{mm\,h^{-1}}$ is applied to near-instantaneous measurements, and there are no spurious smoothing effects due to temporal integration. The difference between dry and wet years is in the occurrence of heavier rainfall associated with convective events (not shown).

Rainfall intensity as a discriminant of rainfall regime is critical for assessing the sustainability of freshwater resources in mountainous regions. For instance, if temperature changes, the

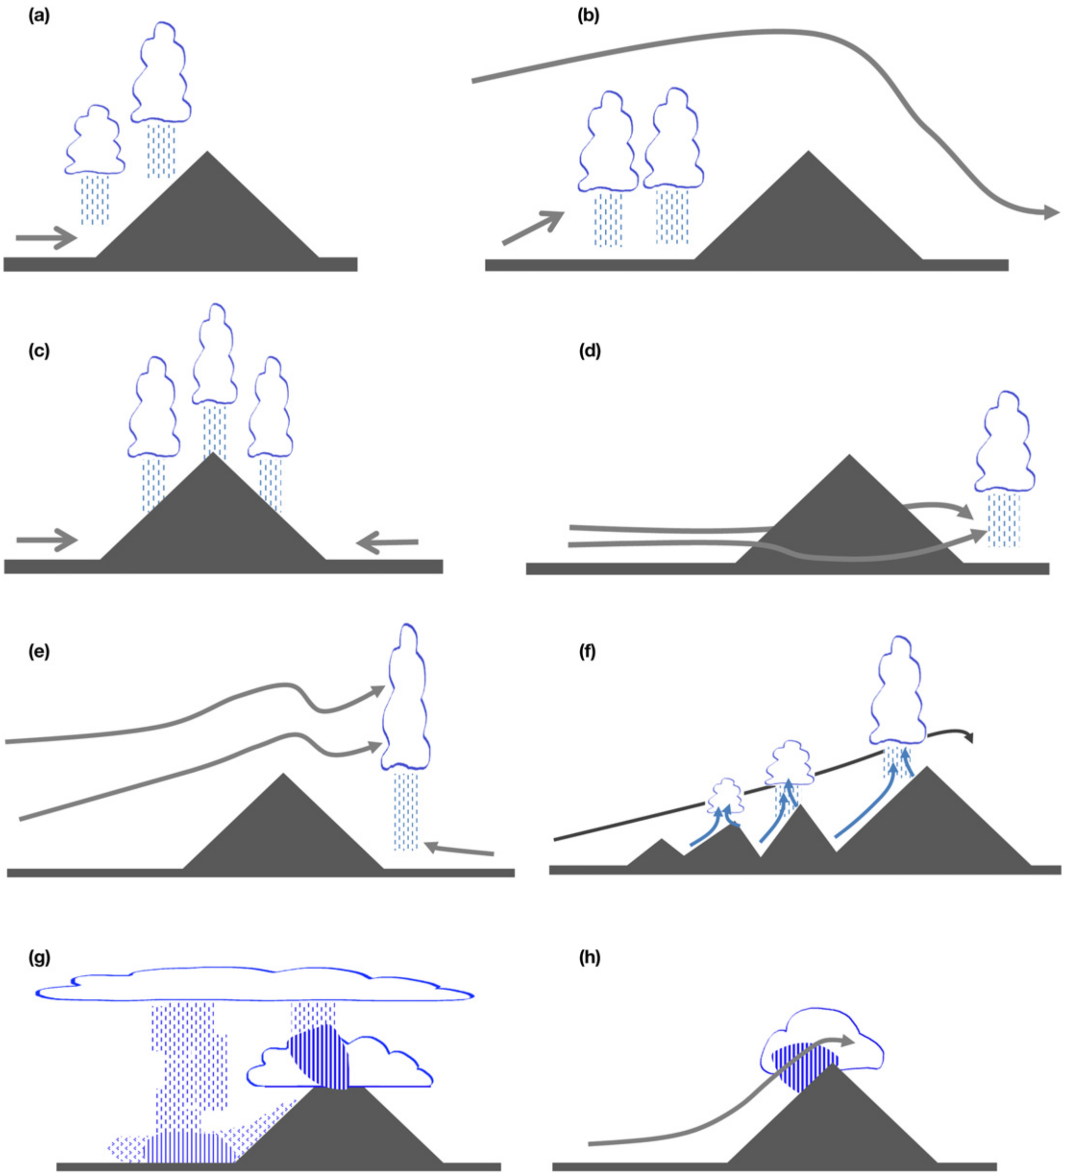

Figure 10 (a) Upslope triggering of convection; (b) upstream triggering of convection; (c) thermal triggering of convection; (d) leeside triggering of convection; (e) leeside enhancement of convection; (f) organization of upslope and leeside triggering and enhancement of convection by complex terrain; (g) feeder–seeder enhancement of rainfall – upstream and upslope enhancement of stratiform rainfall by deep fog and low-level orographic clouds; (e) upstream condensation and stationary deep orographic cloud. Modified after Fig. 12.24 in Houze (1993).

impact depends on how this would be reflected in the diurnal cycles of temperature. Morning light rainfall could be more sustainable than afternoon light rainfall, although light rainfall generally would be expected to decrease because of changes in fog and low-level cloud regimes, lower relative humidity, and increased low-level temperatures in the troposphere. Warm season light rainfall in dry years would be highly susceptible to evaporation. Changes in fog and rainfall intensity affect canopy harvesting of fog and interception of rainfall on the one hand and infiltration and soil moisture on the other. Lower surface soil moisture leads to increased soil and boundary layer temperatures, in a positive feedback loop, which would tend to further increase surface layer temperatures and the dryness of upper soil layers, thus affecting understory and forest floor vegetation at first, and consequently albedo, surface roughness, and depending on drought duration and overall environmental conditions, increasingly depleting soil layers where the deep-rooted canopy systems seek water, ultimately altering system-wide runoff production mechanisms in the soil saturated and unsaturated zones.

5.04.2.2 Snow

Because of complex thermodynamics, mixed-phase physics, and land–atmosphere interactions at the snow–air interface including wind redistribution, the spatial and temporal distribution of snow depth, snow temperature, structure, and snow water equivalent (SWE) are highly heterogeneous and widely

variable in space and time, with very large changes over very small distances. Changes in SWE on the order of 100–300% are not unusual over small distances (tens to hundreds of meters) because of changes in landform, land cover, terrain aspect and insolation, and wind patterns (e.g., Cagnati et al. 2004; Sturm et al. 1995; among others). Traditional measurements that involve coring, digging, or extraction of snow samples are destructive in nature and thus modify snowpack structure on the one hand and are so labor intensive that they cannot be used to sample at the high resolution necessary to characterize the spatiotemporal variability of the snowpack, especially during ripening and melting seasons. Although expensive to install and with high maintenance costs, SNOTEL stations (SNOwpack TELemetry) provide the most rigorous ground-based measurements of SWE based on the weight of accumulated snow (snow pillow) as a function of time [http://www.wcc.nrcs.usda.gov/snow]. There are near 700 SNOTEL sites in the western United States, but the area covered is very large and the stations are very far from each other, thus essentially isolated point measurements. In addition, there are large uncertainties in the measurement due to heterogeneity of snow distribution and internal structure (grain-size distribution, ice layers, etc.) in the snow pillow itself. Other sensors such as cable time-domain reflectometry (TDR) can be installed semi-permanently from the beginning of the snow accumulation season, and thus can monitor the temporal evolution of the snowpack without affecting it. Flat cable TDR applications have been successful over distances up to 100 m (Waldner et al. 2001). The shortcoming is that TDR provides measurements only on the cable direction and along cable length, and therefore measurements over large areas and over rugged and remote terrain are effectively precluded for practical reasons.

Recently, a number of studies have been pursued in the application of ground-penetrating radar (e.g., Granlund et al. 2009). However, snow wetness is especially critical as small changes in volumetric liquid water content can lead to large errors in SWE estimates (e.g., Lundberg and Thunehed 2000). The great opportunity afforded by satellite-based observations is that they provide field estimates at a nominal scale of measurement (e.g., 0.25° × 0.25° MODIS resolution, the Moderate Resolution Imaging Spectroradiometer onboard the Terra and Aqua satellites). On the other hand, SWE errors up to

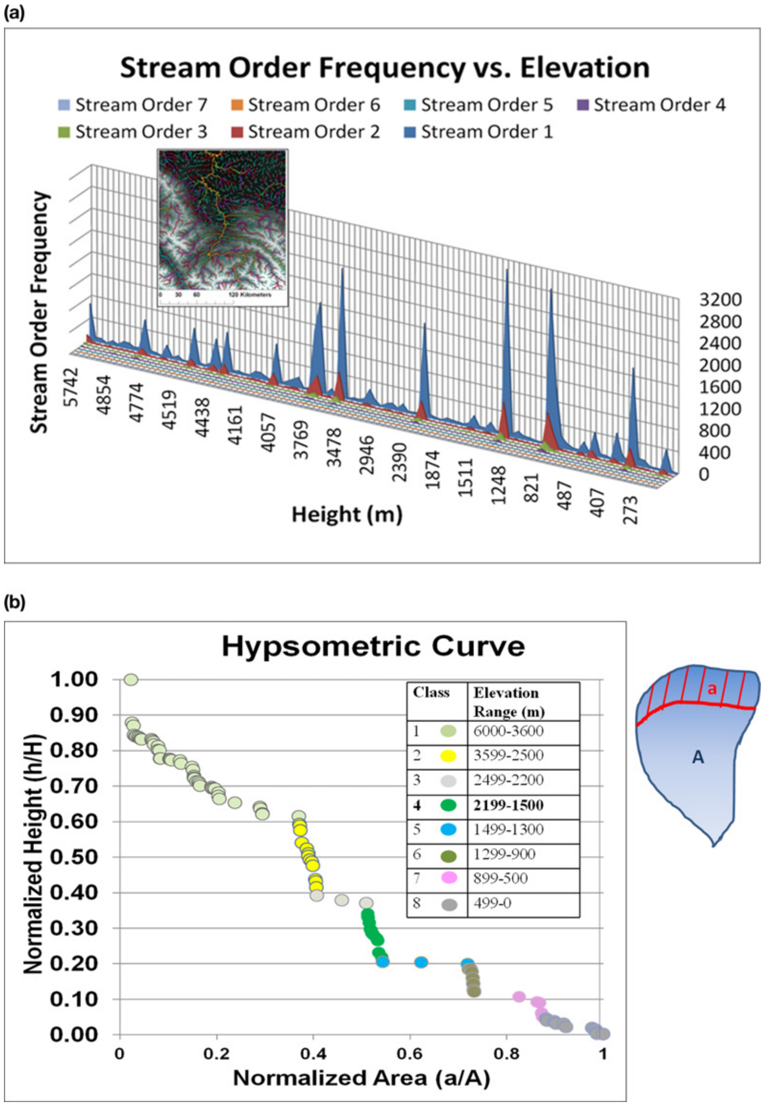

Figure 12 Geomorphic analysis of a digital elevation model (DEM) of the Kospiñata river valley spanning 10.75°–14.65° S and 69°–65° W on the eastern slopes of the Andes: (a) histogram of stream order frequency distribution with terrain elevation (inset is at the center of the DEM analyzed); (b) hypsometric curve describing the distribution of catchment area as a function of elevation from the divide toward the outlet (A, catchment area; a, catchment area above elevation h; H, maximum elevation within catchment).

50% at local places are common because of subgrid-scale variability (snow grain-size distribution, fingering effects and ice layers, wind redistribution, etc., within the satellite sensor footprint) that is not accounted for in operational retrieval algorithms (e.g., Foster et al. 2005; Kang and Barros 2011a,b). To characterize the subgrid-scale variability of snow properties as a function of water content and how that affects the radiometric behavior of snow and ice surfaces is therefore a critical research imperative for systematic remote sensing of snow from space (see, e.g., the recommendations of the Earth Sciences Decadal Survey conducted under the auspices of the Space Studies Board of the National Research Council (NRC 2007)). A distributed system of ground-based autonomous sensors operating at high spatial resolution should provide valuable information to characterize the subgrid-scale variability of the properties of seasonal snowpacks as a function of time, which then could be integrated into retrieval algorithms (Kang and Barros 2010).

5.04.3 Coupled Land–Atmosphere Interactions and Mountain Ecohydrosystems

We take the blue and green water framework (Falkenmark and Rockström 2006; see their Figure 1), where blue water encompasses both surface runoff water and groundwater to address the question of water resources and sustainable ecosystems in mountainous regions. Recent modeling studies of the diurnal cycle of rainfall in mountainous regions around the world (e.g., Iwasaki 2003: Japan; Pistotnik and Haiden 2004: European Alps; Yang et al. 2004: Tibetan Plateau; Bushan and Barros 2007: Sierra Madre in Mexico) suggest that ET and

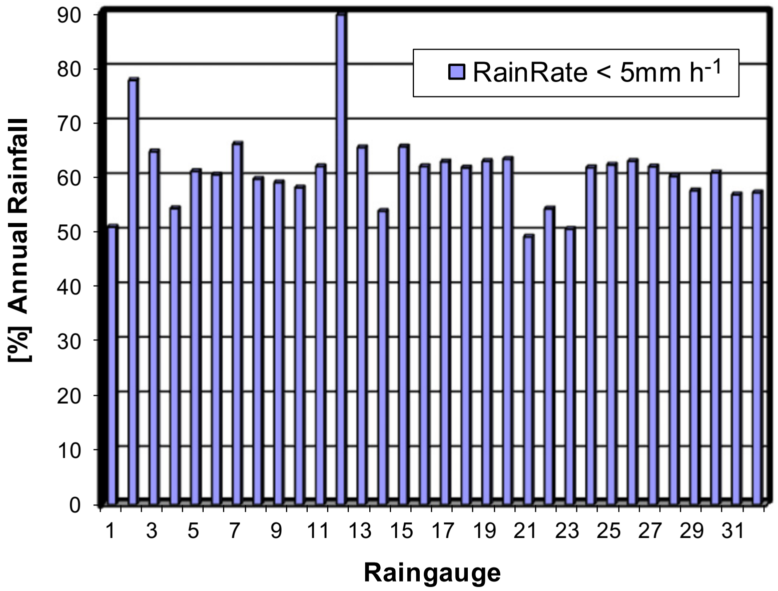

Figure 13 Light rainfall ($<5\,\mathrm{mm\,h^{-1}}$) 2008–11 in the Great Smoky Mountains expressed as a fraction of the total annual accumulation.

mountain–valley moist transport have a strong influence in the diurnal cycle of precipitable water (PW) and convective available potential energy (CAPE), thus ultimately affecting the location and timing of the onset of convection in daytime, and establishing conditions for late evening convective activity. While such studies have been conducted for different synoptic environments and moderate topography (500–1500 m elevation differences), we also found that the diurnal cycle of rainfall in the Himalayas exhibits similar features, including a nocturnal maximum that follows concurrent local maxima in PW and CAPE independently of the strength of monsoon forcing (Figure 14; Lang and Barros 2002; Barros and Lang 2003). This suggests the ubiquity of a dynamic link between topography, the spatial variability of ET (and soil moisture) via surface sensible and latent heat fluxes, and the spatial organization of rainfall by which the mountains modulate precipitation processes (Monteith 1995; Pielke 2001). Interactions between land cover and cloudiness are well known from satellite data (O'Neal 1996; Rabin and Martin 1996; Wielicki et al. 1993). The observed collocation of the spatial patterns of the diurnal cycle of cloudiness and orographic precipitation with specific terrain features and land cover patches in the tropics provides strong physical evidence to the hypothesis (1) that landform, land-cover patterns, soil moisture, clouds, and precipitation are dynamically interconnected on steep altitudinal gradients and (2) that ET plays a key role in the spatial organization of precipitation at the ridge-valley scale, even in the presence of strong monsoon (large-scale) forcing (Foster 2001; Barros et al. 2004, 2006). In the eastern slopes of the Central Andes, we hypothesize that interactions among moisture advection from the Amazon basin at lower elevations and upslope fog at higher elevations and cumulus clouds organized by ridge-valley circulations explain the persistent rainfall throughout the day at all elevations, albeit with strong decreases in rainfall intensity with elevation.

In the absence of synoptic forcing, orographic precipitation data typically show an afternoon peak over ridges associated with diurnally forced upslope flow. While such a peak is visible in the Himalayan data (Barros et al. 2000), its relative contribution to the observed monsoon rainfall is small in the region, especially at low elevations and in the valleys (Barros et al. 2000, 2004). Instead, Barros et al. (2000) noted a nocturnal peak in rainfall, just past midnight. Other researchers have noted this regional phenomenon as well (Ueno et al. 2001), and we also find it in the Andes. On the other hand, in the Central Andes, in the Amazon-Manu transect, the early afternoon rainfall peak based on preliminary data appears to account for up to 20–30% of all rainfall. One possible explanation for this difference is that the Amazon provides a sustained moisture source for the eastern slopes of the Andes, even in the absence of large-scale advection, whereas no such equivalent regional moisture source exists in the Himalayas. This finding motivated the Monsoon Himalaya Precipitation Experiment (MOHPREX; Barros and Lang 2003).

During MOHPREX, the diurnal evolution of thermodynamic conditions in the lower troposphere from radiosondes launched at Besisahar in the central Himalayas shows normal diurnal heating and cooling of the atmosphere, which is perhaps lagged a bit by the high moisture levels. Also, there is a daily replenishment of moisture occurring at all levels after the nocturnal depletion by rainfall. The timing of these two processes leads to the observed diurnal evolution of CAPE and PW (Figure 14). The net daily depletion of atmospheric moisture was estimated as ~6 mm on average (Barros and Lang 2003). This moisture supply must be restored daily through local ET and through large-scale advection. ET estimates varied between 0.5 and 6 mm per day, corresponding to an average daily evaporative fraction (ET/rainfall) on the order of 0.15. At lower elevations, which do not see rainfall during the day, the evaporative fraction corresponds to average premonsoon values of about 0.35 when soil moisture availability is not a limiting factor. Although spatially variable, the observations imply that 15–35% of the daily surface ET is locally or regionally recycled (Barros and Lang 2003). This is consistent

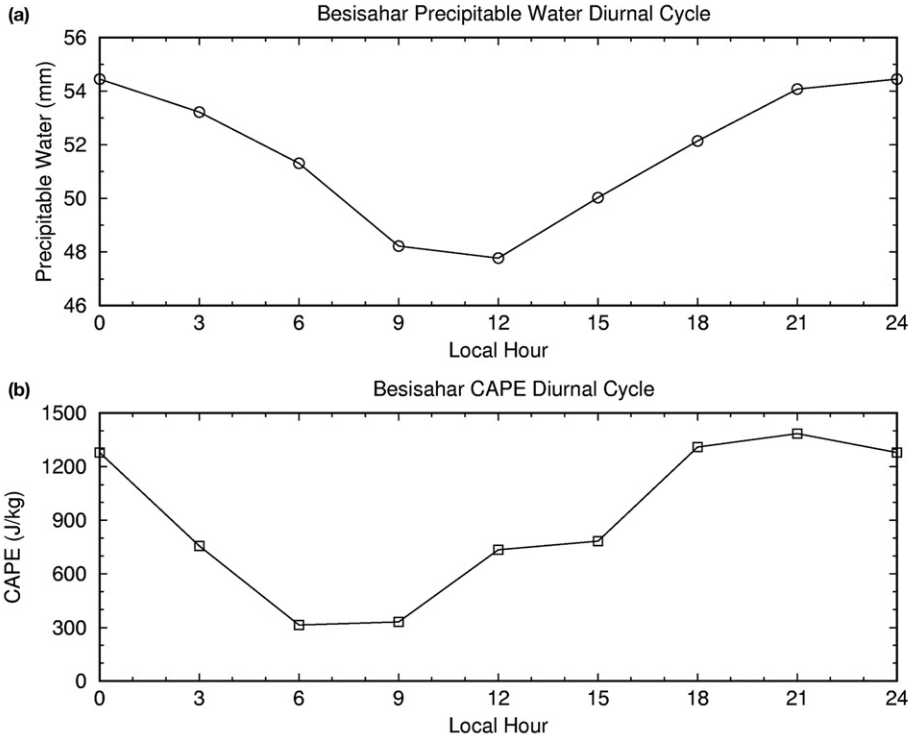

Figure 14 Diurnal cycle of (a) precipitable water (PW) and (b) convective available potential energy (CAPE) in central Nepal at Besisahar during MOHPREX (Monsoon Himalaya Precipitation Experiment). Adapted from Barros and Lang (2003).

with results by Iwasaki and Miki (2001), Iwasaki (2003), Pistotnik and Haiden (2004), and Bushan and Barros (2007), elsewhere who attributed a daytime increase in PW on the order of 2–5 mm associated with surface ET and mountain–valley circulations alone. Low-level moisture resulting from ET is advected upslope and up valley during daytime to increase the humidity in the mixed layer along ridges and at the headwaters of interior river valleys when large-scale moisture advection is absent or otherwise cannot penetrate because of blocking effects (Barros et al. 2006).

Pistotnik and Haiden (2004) investigated the effect of surface ET in the central parts of the Alps by switching off evaporation as a moisture source to the atmospheric boundary layer (ABL) in the numerical simulation of a storm case (LE was set to zero only where it represents a water source for the atmosphere, but nowhere else). In the unmodified simulation, convective precipitation starts in the late morning, around 09 UTC (Coordinated Universal Time), and is initially strictly tied to orographic features, where orographically induced convergence of the near-surface wind coincides with moisture advection. It takes two or three more hours until convection starts in the central parts of the Alps that are not in the path of moisture advection from adjacent basins or broad valleys. This scenario is very similar to our hypothesis about the role of moisture advection from the Amazon in the Central Andes. By contrast, in the experimental run without ET input, Pistotnik and Haiden found that cloud bases were significantly higher (by up to 1 km) than in the reference run. In the inner mountain areas, rainfall was completely absent, indicating that where large-scale moisture advection did not penetrate, surface ET was the essential humidity source. One interesting result of this study is the suggestion that progressive drying of the ABL during the day allows stronger daytime heating over the mountains and intensifies wind convergence over the ridges, eventually constraining precipitation to the locations where convection is favored and low-level moisture can be replenished by regional transport. Although these simulations were conducted in the context of numerical weather prediction without considering explicitly altitudinal gradients of vegetation, this behavior is consistent with the presence of the secondary afternoon peaks in rainfall, PW and CAPE at high elevations on the ridges in the Marsyangdi network in the Himalayas, and first observations in the Central Andes, and provides support for our hypothesis regarding the role of vegetation on the diurnal cycle of orographic clouds and rainfall, where ET from the elevations covered with rain forest may be a critical moisture supply to support late afternoon fog and cloud formation at high elevations in the cloud forest.

Yang et al. (2004) illustrate how evaporative cooling of rainfall may interact with mountain–valley circulations to affect deep convection using a 2D simulation in the Tibetan Plateau. Late morning or early afternoon convective rainfall on the ridges evaporates and cools the lower levels of the troposphere, and can force downslope flows that interact with the preexisting upslope flows to establish convergence away from the ridge, eventually triggering convective activity toward the valley. Solar heating and compensating subsidence over the ridges would then establish conditions to drive upslope flow again to the ridges, leading to the establishment of a ziz-zag pattern in the spatial distribution of rainfall from ridge to valley back to ridge. This mechanism might explain the 2–3 h lags in early evening rainfall between high and low elevation stations in the Marsyandi network when the synoptic-scale forcing is weaker (Barros et al. 2000; Barros and Lang 2003), and it is also found in the preliminary data from the Andes.

In the absence of large-scale moisture convergence, PW over the mountains should begin to decrease in the late afternoon and evening as surface latent heat fluxes progressively decrease and the atmosphere over the valley becomes colder and dry because of baroclinic compensation (Kimura and Kuwagata 1995). However, while ridge precipitation leads valley precipitation during the day and into the evening, this is not the case at nighttime. The nocturnal maximum over the ridges and against the orographic divide is observed either in sync with the nocturnal peak in the valley at low elevations (Bushan and Barros 2007), or 1–2 h later for strong and weak synoptic forcing conditions, respectively. Research toward clarification of these processes is needed.

5.04.4 Climate and Environmental Change Vulnerabilities of Mountainous Regions

5.04.4.1 Headwater Catchments and Water Resources

In mountainous regions, orographic processes control precipitation, and therefore, headwater streams are critical in capturing rainfall directly and through surface and surface runoff mechanisms to be delivered to valleys and reservoirs downstream at lower elevations. Because most rainfall tends to occur at specific places in the landscape according to regional hydroclimatology and topography (Barros et al. 2004), headwater catchments are also critical in terms of aquifer recharge in mountainous regions (Barros 2008). Headwater streams also provide important ecosystem services. For example, benthic macroinvertebrates in headwater streams are food for small mammals and for fish communities downstream, and also perform the important function of breaking down coarse organic matter, such as leaves and twigs, and releasing fine organic matter. When the benthic macroinvertebrate community is changed or extinguished in an area, even temporarily, as occurs during land use changes, it can have repercussions in many parts of both the terrestrial and the aquatic food web. Because there is little upstream or stream-to-stream migration of benthic macroinvertebrates, once headwater populations are eliminated, there is little hope for restoring a functioning aquatic community (Silsbee and Larson 1982). In addition to macroinvertebrates, these streams support diverse populations of plants and animals that face similar problems if streams are disturbed. In summary, headwater streams control flooding, recharge groundwater, maintain water quality, reduce downstream sedimentation, recycle nutrients, and create habitat for plants and animals.

Light rainfall defines, the regional background hydrometeorological regime in the Southern Appalachians and provides the baseline freshwater input into the regional natural hydrosystems, including the minimum water availability requirements for existing ecosystems. Here, we make the case that light rainfall is a lifeline process essential for the sustainability and resilience of mountain ecosystems first, and adjacent lowlands next (in the Piedmont of North Carolina average rainfall fraction also varies between 30 and 40% of the annual net, although there is a stronger seasonal effect, especially in the summer). Furthermore, the frequency of light rainfall peaks in the morning, especially in the summer and fall seasons when there is more frequent afternoon convection. Rain drop size distributions (DSD) obtained with microrain radar (MRR) profiles at different elevations suggest that morning light rainfall may be attributed to seeder–feeder interactions among valley fog, low-level orographic clouds, and regional stratus, whereas radiation fog likely plays an important ‘feeder’ role in the evening (Barros and Lettenmaier 1994; Prat and Barros 2010a). In the Andes, we hypothesize that upslope fog advection and blocking at elevations between the topographic divide support light afternoon rainfall above 3000 m.

Figure 15 shows examples of two 1-year long experimental simulations for a headwater catchment in the Great Smoky Mountains with and without light rainfall, everything else being the same. Note the reduction in cold season streamflow response overall, especially from February through April before convective activity in 2009 picks up. This reduction in streamflow and reduced flashiness has strong implications for riverine ecosystems and associated river ways. Changes in streamflow reflect changes in subsurface flow, soil moisture distribution, and water table levels across the watershed.

Changes in root zone soil moisture and associated changes in surface latent and sensible heat fluxes and surface layer humidity can in turn have a significant impact on vegetation cover. Although there is ample evidence in recent decades of changes in tree species in the Great Smoky Mountains National Park, North Carolina, Iverson and Prasad (2001) relying on statistical models of vegetation–climate patterns to examine the impact of five likely alternative climate regimes based on GCM simulations found no cause–effect relationship between climate and species richness. As mentioned earlier, this can be explained by the coarse spatial resolution of such climate models that cannot capture the altitudinal variations in climate as well as spatial variations in temperature, light availability, precipitation, and soil moisture states in mountainous regions. Using field data from nearly 20 years instead of model results, Clark et al. (2011) found that most sensitivity was to light availability. Because of the relationship between fog and light availability in the Great Smoky Mountains and that between fog, rainfall, and soil moisture, the surface energy budget and summer drought are strongly linked to climate and the water cycle, and one would expect significant changes in fecundity and increased vulnerability of tree species in the region of study because of changes in the precipitation regime (Zhu et al. 2011). Therefore, sensitivity to the governing hydrometeorological regime is especially important, as it articulates the need to explicitly include forests in mapping the physical hydroconnectivities of the landscape.

5.04.4.2 Land Conversion

Over the past 30 years, major land use transitions in mountainous regions consisted first of conversion of low-elevation croplands for urbanization, uphill expansion of agriculture, and urbanization through direct conversion of previously pristine forested areas to urban areas and to new housing developments. First, new development spreads in the valley

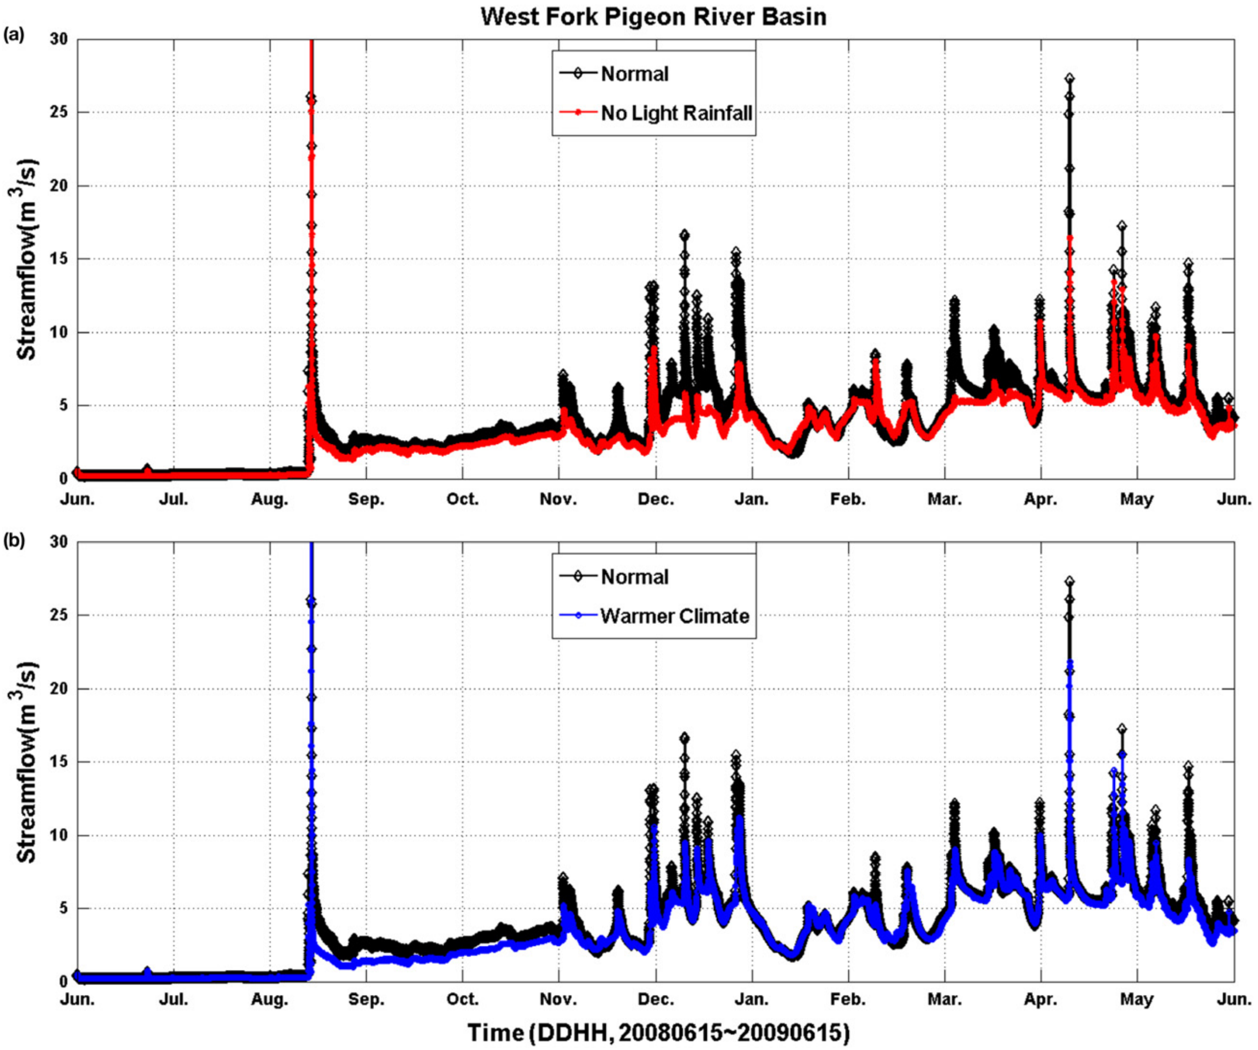

Figure 15 Rainfall-runoff sensitivity to potential changes in regional hydroclimate in a headwater catchment (~75 km^2 areal extent) in the Great Smoky Mountains, North Carolina, USA: (a) Jun 2008–May 2009, assuming all light rainfall ($<$3 mm h^{-1}) evaporates before reaching the ground; (b) Jun 2008–May 2009, assuming there is a contraction in the amplitude of the diurnal cycle of air temperature, which results from an increase of 2 °C at nighttime (6 p.m.–6 a.m. LST).

often where the floodplain is wider at the confluence of small tributaries, and then it penetrates upward the surrounding slopes. Land conversion in the next decades is expanding to the ridge areas, and in many regions of the world (e.g., the mid-Himalayas) this is the case already. Depending on local conditions, this results in increasingly fragmented landscapes.

Loss of natural vegetation cover and fragmentation of natural landscapes diminishes the landscape capacity to provide important ecosystem services, and when placed in realistic hydrogeological contexts and given the specificity of soil types and soil structure at local places, changes in land cover and land use strongly affect key hydroconnectivities and have a major impact on the water budget of headwater catchments. Using a coupled surface–subsurface model with dynamic vegetation at 1 km^2 to reconstruct the drought of 1988 and the wet year of 1993 in the Central Appalachians, Yildiz and Barros (2007) found that the two most important parameters controlling rainfall–runoff response on an event basis as well as the water budget at seasonal and annual time scales were vegetation fraction and leaf area index (LAI). On the other hand, warming of the lower troposphere can have a strong impact on fog–cloud and fog–cloud–rainfall interactions. The direct effects of fog and low-cloud suppression include changes of light and rainfall regimes, whereas the indirect effects have to do with the surface water and energy budgets and vegetation dynamics including vegetation replacement/succession (Figure 16). In Costa Rica, land use change associated with land use conversion from rain forest to agriculture in the lowlands has been linked to local changes in cloudiness and the elevation of cloud base over adjacent mountains (Lawton et al. 2001; Nair et al. 2003). We hypothesize that similar effects might occur elsewhere, for example, on the eastern slopes of the Andes due to clear-cutting in the Amazon.

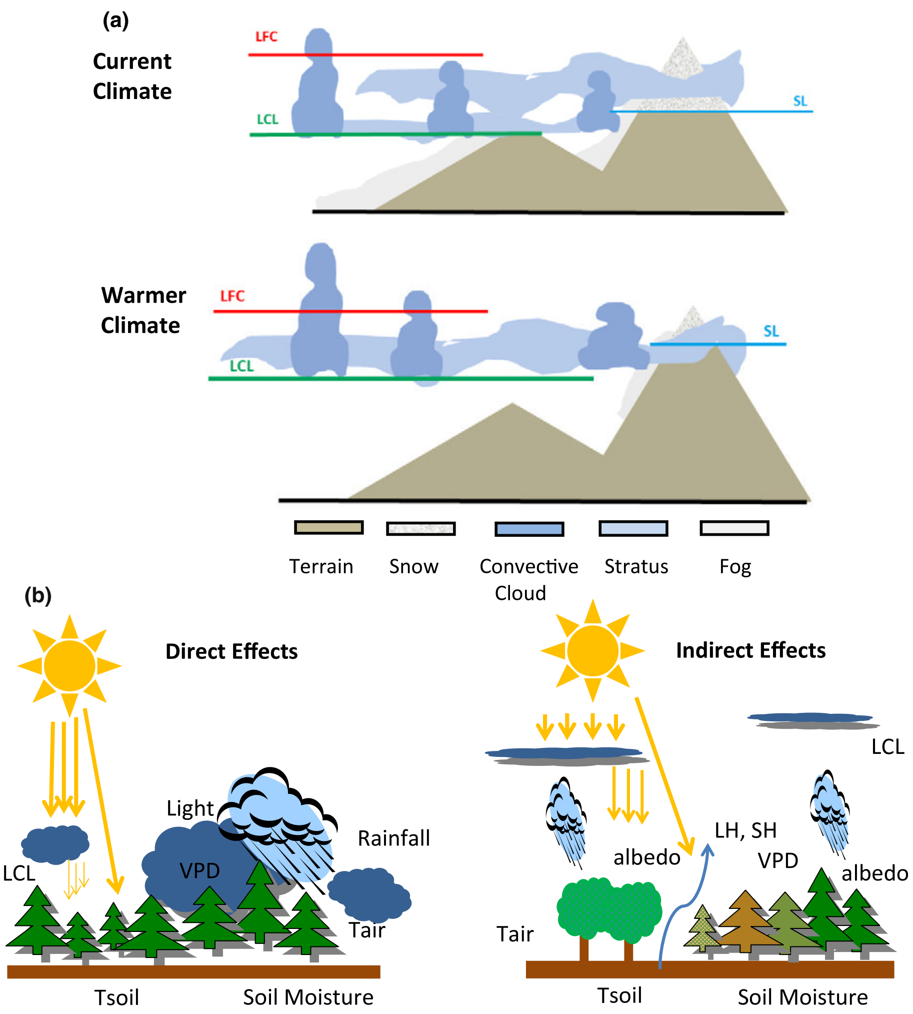

Figure 16 (a) Conceptual representation of changes in fog–cloud–rainfall interactions given an increase of regional lower troposphere temperatures that would impact the light rainfall regime. (LFC, level of free convection; LCL, lifting condensation level; SL, snow line); (b) Feedback of changes in fog–cloud–rainfall interactions toward increased aridity: left panel – direct effects (land surface forcing) include changes [+] in space–time patterns of light availability and incoming shortwave and long-wave radiation [+], vapor pressure deficit (specific humidity) in the lower troposphere [−], and rainfall [−] and air temperature [+]; right panel – indirect effects (land surface response and impacts on the planetary boundary layer) include changes in vegetation type (root structure, canopy, and color), albedo [−] and emissivity [+]; changes in latent [−] and sensible heat fluxes [+]; changes in soil temperature [+]; changes in soil moisture [−] and runoff [−]; changes in fog and low-level cloud morphology (thinner higher clouds, reduced fog) [−]; and LCL height [+] (VPD, vapor pressure deficit; Tair, air temperature; Tsoil, soil temperature; LH, surface latent heat flux; SH, surface sensible heat flux).

There is a vast literature in ecology addressing impacts of land conversion and the different modes of landscape fragmentation either due to natural changes or from forest clear-cutting practices (see review by Collinge 2009). Syphard et al. (2005) studied the effect of urban encroachment in the Santa Monica mountains in California. They found that development on steep slopes (>60%) lead to the largest habitat loss and more intense landscape fragmentation and connectivities. Various modes of spatial land use–land cover (LULC) change, including shrinkage, bisection, fragmentation proper, and perforation, will have different impacts on the dynamics of species competition and spatial variability. The challenge is to adaptively manage land conversion by preserving key hydro-connectivities including local microclimates, recharge areas, functional topsoils, and biodiversity, dampening indirect effects.

Besides human activities and climate, natural hazards, and in particular strong winds, fires, and landslides, can be important agents of rapid LULC transition. The vulnerability of landscapes to rapid disturbances is always high at short time scales, but moderate in the medium and long term if light and moisture regimes are conducive to recovery.

5.04.4.3 Mountain Snowpacks

Snow and ice are tightly connected to the climate at continental and global scales. Snow and melt processes are critical to characterize the mass balance of Arctic sea ice, which has been thinning at unprecedented rates (Kwok and Untersteiner 2011). The impacts from changes in the climatology of spatial patterns of temperature in cold regions are being felt at the global scale (Thompson et al. 2011; Koç et al. 2009). For instance, changes in snow cover, SWE, and winter–spring seasonality over the Eurasian region affect surface albedo and soil wetness, and strengthen or weaken the large-scale land–ocean temperature contrasts, including changes in Southeast Asian monsoon rainfall (Barnett et al. 1989; Qian et al. 2003, and many others) and changes in phytoplankton concentration in the Arabian sea (Goes et al. 2005). Feedback among clouds and snow-covered areas has a significant effect on the surface energy budget and the organization of local and regional-scale circulations. Global model predictions of snow cover-related feedbacks on the surface energy budget are difficult to assess because of the large uncertainties in predicting frozen precipitation amounts and spatial distribution. Even at weather-event scales and relatively high resolution, modeling uncertainties are very large, which prevent definitive impact studies as shown for the spatial distribution of albedo in **Figure 17** for two simulations using the Weather Research and Forecasting (WRF) 3.4 model at 18 km resolution, with everything being the same except the forcing used to drive the boundary conditions (**Figure 18**).

At high latitudes, it has been shown that the net daily radiation balance over snow surfaces is larger under cloudy sky conditions because of the increase in incoming long-wave radiation (Ambach 1974; Zhang et al. 2004). The magnitude of this enhancement depends on the cloud base, cloud base temperature, and cloud thickness, whereas an increase in air temperature accompanied by an increase in the moisture-holding capacity of the atmosphere can lead to significant changes in snowpack distribution due to the combination of two effects: (1) push the snow line to higher elevations (the elevation difference between locations of small glaciers in the Himalayas between current climate conditions and the last Glacial Maximum is on the order of 1000 m (Barros et al. 2006; Diaz et al. 2004)) and (2) more moisture at high elevations would increase snowfall and lower the cloud base, increase cloud depth and cloud cover, therefore warming the snowpack, increasing the likelihood of avalanches during snowpack ripening, and thus accelerating the onset of the melting season. This increases soil wetness early in the year, leading potentially to increased ET and reducing the contribution of snowmelt to river runoff or at least shifting it from the summer to spring. The impacts on agriculture and land management activities generally stem not only from changes in quantity but also, perhaps more critically in certain regions of the world, in timing of runoff and groundwater recharge (e.g., Koç et al. 2009; Lowry et al. 2010).

In Asia alone, eight of the world's largest river basins (from west to east, the Syr Darya, the Amu Darya, Tarim, Indus, Ganges, Brahmaputra, Mekong, Yangtze, and Yellow River) affecting roughly 1.5 billion people depend on glaciers and snow at high elevations to maintain river flows (see Figure 21 in Nellemann et al. 2009). In the western United States, more than 70% of the water resources are generated during the spring melting season and subsequently stored behind dams for a broad range of water uses during the dry season (Stewart et al. 2004). Fundamental challenges in snow measurement, including specifically the need for high-resolution estimation of snow wetness and snow density, point out the importance of the so-called transition zone in mountainous regions where the fractional contributions of snow and rain to the total annual precipitation are highly variable in space and time, and wetter and warmer snowpacks during the cold season are thus more unstable. Trends in historical observations and simulated changes from GCM simulations suggest that large shifts in the spatial and temporal availability of freshwater resources from snow could occur (e.g., Knowles et al. 2007; Brown and Mote 2008; Pepin and Lundquist 2008; Stewart et al. 2004; Stewart 2009). Yet, the density of climate observations is the lowest for

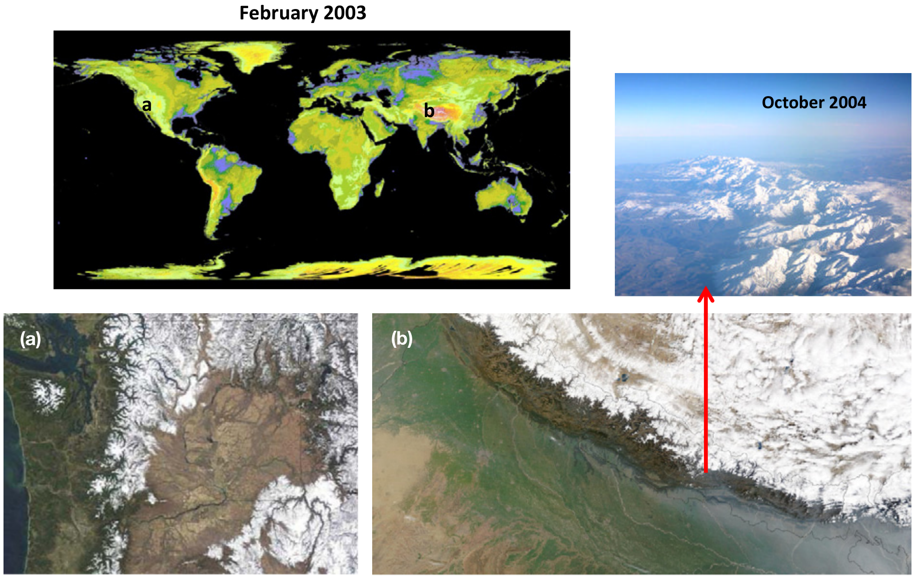

Figure 17 Snow cover distribution in February 2003 observed using the MODIS sensor on the Terra satellite: (a) Columbia River basin; (b) Himalayan range. Source: MODIS–NASA; Photo: http://www.himalaya-foto.ru.

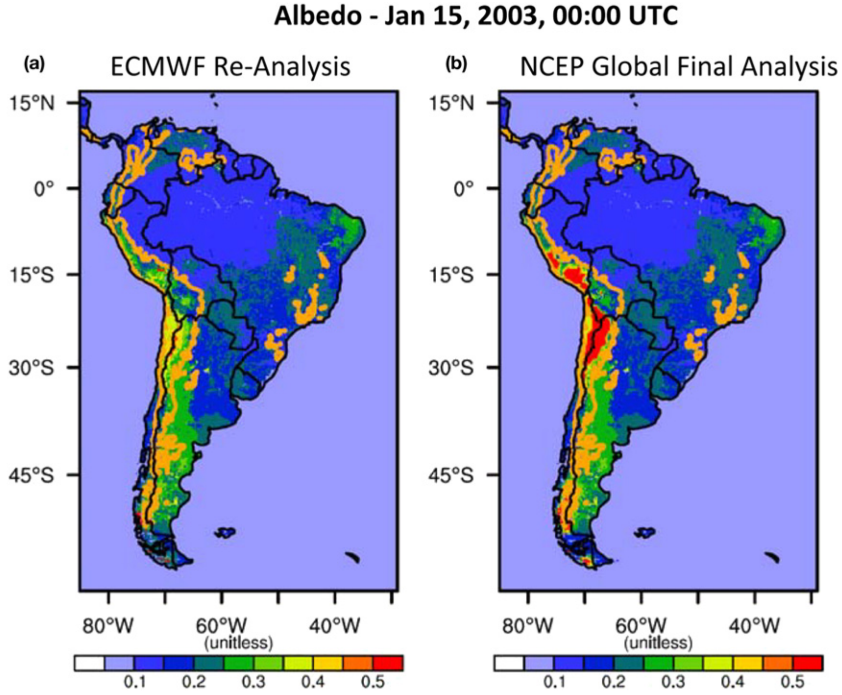

Figure 18 Snow albedo over the Andes for a WRF V.3.4 (weather research and Forecasting model) simulation of during the wet season in model simulations using two different large-scale forcing data sets: (a) ECMWF Reanalysis (ERA) and (b) NCEP Global Final Analysis (FNL). The differences in albedo reflect the different distribution of frozen precipitation in the two simulations, and provide a measure of the uncertainty in surface energy balance calculations in the Altiplano, which in turn affects large-scale circulation.

frozen precipitation and snow and ice accumulation including the rain–snow transition elevation (Viviroli et al. 2011, Figure 19).

5.04.4.4 Water Resources Governance

Rogers and Hall (2003) define water governance as the range of political, social, economic, and administrative systems established for the development and management of water resources and water services at all scales (Figure 20). It needs to be considered at basin and subbasin scales, and within sectors (e.g., agriculture, urban water supply) and intersectorally, and should encompass the management of the land use and hydroconnectivities within a basin that affect the characteristics of the resource downstream. It includes establishment of rules, responsibilities, operating mechanisms, policies, and user and official accountability systems. Effective governance is that which provides water for livelihoods and economic growth, yet maintains a sustainable environment. Each river basin has its own physical, social, environmental, and economic characteristics; is at a particular level of development; and has its own unique form of formal and informal governance systems in place, which are characterized by the particular social, cultural, and political setting of that basin. At the same time, many of the world's basins are becoming increasingly over-allocated, or stressed in other ways, such as through increased population density, urban sprawl, agricultural expansion, and pollution (Vörösmarty et al. 2010). In the case of mountainous regions, the challenges due to progressive encroachment of anthropogenic activities upon headwater basins that control freshwater resources and thus water supply downstream may differ in the details on account of regional specificities, but not in substance, and the stressors are fundamentally the same in North and South America as in Asia.

It is increasingly acknowledged that even in the least developed parts of the world there needs to be a basic platform of water-systems infrastructure for effective water governance to support the needs of the society and economy (Grey and Sadoff 2007). In the United States, the water resources governance tends to be highly codified, in terms of regulations, rules, and laws, with strong yet relatively diffuse institutions. Missing in terms of both infrastructure and institutions in the US and elsewhere is the capacity to adapt to change, especially when change is fast and driven by multiple stressors: climate variability and longer term change, population growth, economic development, and natural resource management practices and policies. Active involvement of stakeholders in the decision-making process, however, often only takes place in terms of protecting and ascertaining water use rights locally especially when crisis strikes (e.g., drought). A contrasting example is the Ganges River in South Asia, where patterns of water flow and utilization in the basin are changing, and in some subbasins very rapidly. Water governance in the smaller catchments is relatively nonexistent apart from basic community level efforts and, at the river basin scale, is defined based on macro considerations by a concentrated authority at high government level.

Sustainable water systems function optimally in the context of evolving human and natural landscapes to capitalize water availability at short time scales and to balance water demand and ecosystem services over long time scales. It is well accepted

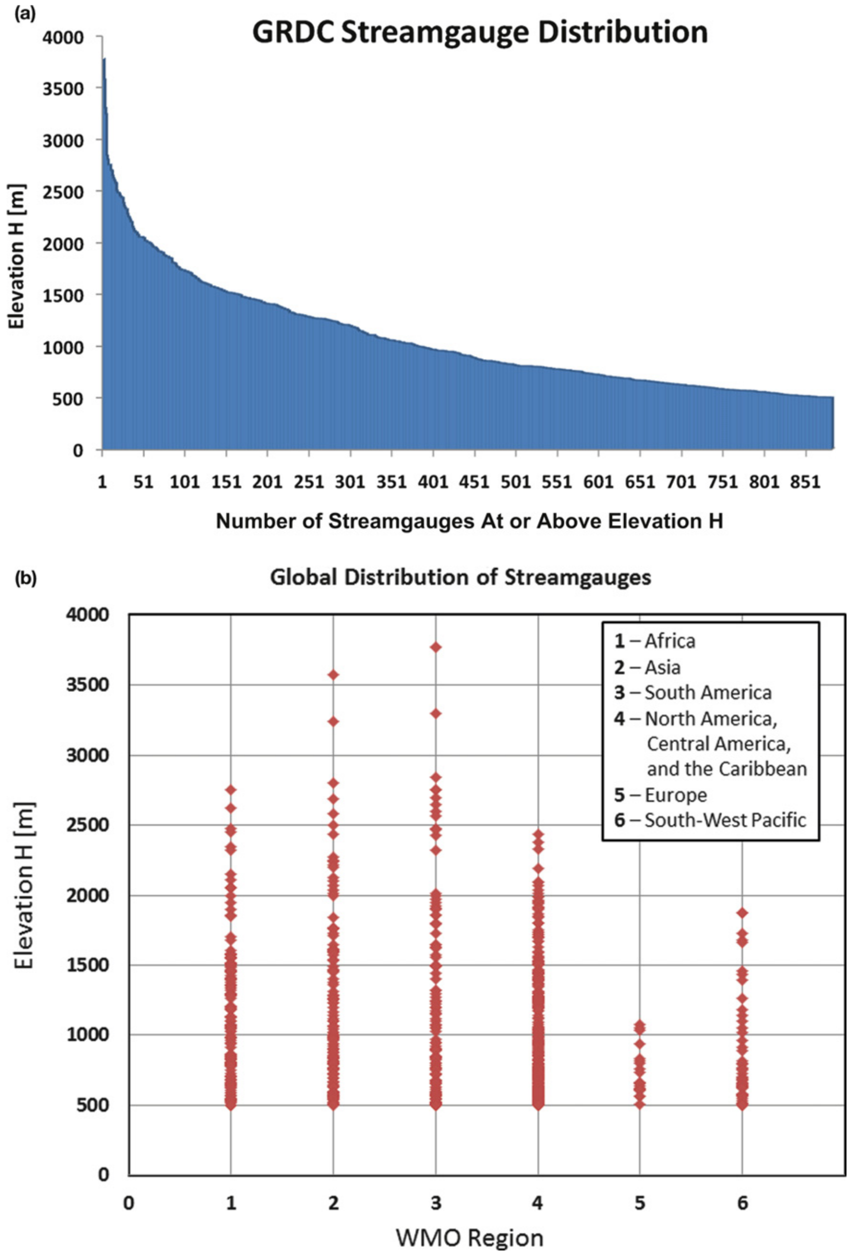

Figure 19 Global distribution of Streamgauges: (a) as a function of elevation; (b) for each elevation as a function of World Meteorological Organization (WMO) regions. Source: http://www.bafg.de/GRDC/EN.

that this can be accomplished only by combining the best science and predictive models with vigorous, participatory water governance spanning a wide range of spatial and temporal scales and policy horizons (Falkenmark and Rockström 2006). Although access to the necessary financial resources to adapt infrastructure and the institutions may be less of a challenge in the United States, the ability to adapt at a rate and in a manner that reflects the best end-to-end understanding of the underlying water systems is lacking. Effective water management that integrates both society and ecosystems needs is key to climate adaptation. Besides the importance of relying on science-based predictive models, there remain important disconnects between the technical and science-based knowledge of water resources management and the broader governance aspects, such as the participation of the community, stakeholder involvement in the basin management process, relationships between the water resources systems, and changes in key sectors, such as industry and agriculture. Where the capacities and resources are available, nimble response to change by reevaluating zoning plans, switching cropping patterns, revisiting reservoir operation plans, development of new storages and other infrastructure, including early warning systems, and enhancing institutional arrangements can result in sustainable adaptation.

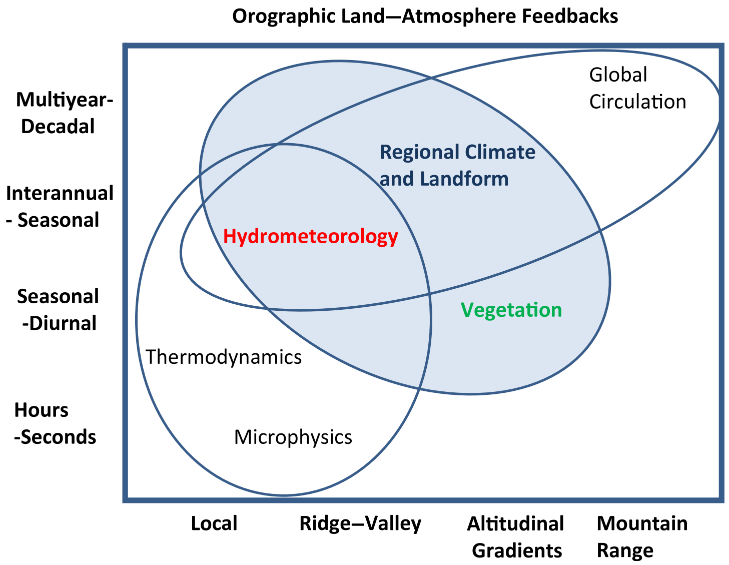

Figure 20 Schematic of processes and scales of orographic land–atmosphere interactions and direct and indirect fog–cloud–rainfall feedbacks.

5.04.5 Synthesis

Mountains play a critical role in modulating the water cycle at regional scales beyond the spatial presence of the mountain proper reaching out to the adjacent plains of the world's largest river basins. Orographic effects negotiate the regional harvest of large-scale moisture transport at seasonal scales, and complex space–time patterns of landform and vegetation determine the diurnal cycle and 3D organization of mountain microclimates (Figure 20). Local fog–cloud–rainfall interactions conspire to sustain the light and moisture availability regimes that nurture mountain vegetation in a crescendo orchestrated along altitudinal gradients depending on increasingly more delicate feedbacks with elevation. In this chapter, the case was made that fog and light rainfall are the water lifeline of mountain environments, whereas extreme events are the agents of short-term disturbances. The challenge of adaptation to change and sustainability of mountain freshwater resources hinges on our ability to understand and manage the dynamic balance between disturbance and resiliency, and this includes environmental policy and water and land governance matters. In mountains, perhaps more critically than anywhere else, and paraphrasing Falkenmark, a land use/land cover decision is a water decision. The reverse is also true. Mountains remain among the most poorly observed environments in the planet. Improving fog, clouds, and rainfall observing systems, yet so sparse in mountainous regions, is essential to understand and to make sound sustainable water decisions.

5.05.1 Tropical Montane Cloud Forests and Their Relationship to Water Input

Tropical montane cloud forests (TMCFs) are unique tropical ecosystems that occur as narrow altitudinal bands between 800 and 3500 m on mountains in the continents of Africa, America, and Asia and in equatorial Oceania (Bubb et al. 2004; Kapelle 2004; Bruijnzeel et al. 2011) (**Figure 1**, also see **Figure 1** of Bruijnzeel et al. 2011). The defining characteristic of TMCFs is persistent cloud cover/fog at the vegetation or ground level that ensures that the tree crowns are regularly in contact with cloud water. The cloud water in turn contains drops of an entire spectrum of sizes from suspended droplets to falling rain-sized droplets. Cloud water directly condenses on the vegetation surface in TMFCs as precipitation. This phenomenon is variously referred to in the literature as 'horizontal precipitation,' 'direct interception,' or 'cloud water stripping.' The cloud water that is deposited regularly on the vegetation surface is primarily from orographically lifted air masses that cool to form the clouds (**Figure 2(a)**), although orographically lifted advection fog, sea fog, steam fog, or radiation fog could also provide a source for horizontal precipitation (Scholl et al. 2010).

The singular distinguishing feature of regular immersion in clouds and cloud water input to TMCFs has important implications to vegetation characteristics, vegetation productivity, nutrient uptake, soil and litter composition, and a positive water balance (**Table 1**). This process is especially important for dependable streamflows in areas downstream that have little dry-season precipitation but where cloud forests are present upstream (Bubb et al. 2004). This unique feature of TMCFs also results in higher species richness and higher biological endemism within the TMCF (Foster 2001; Bruijnzeel et al. 2011). Three types of TMCFs are now recognized: lower montane cloud forest, upper montane cloud forest, and subalpine cloud forest (Bruijnzeel et al. 2011). The transition from lower to upper montane cloud forest coincides with the level where cloud condensation becomes more persistent, whereas that from upper to subalpine TMCF occurs at the altitude where the average maximum temperature falls below 10 °C (Bruijnzeel et al. 2011). The current estimates of global spatial extent of TMCFs vary widely from 21 5000 km^2 to 2.21 million km^2 (Bruijnzeel et al. 2011), partly due to the difficulty of identifying which tropical forests are regularly cloud immersed forests, although remote sensing techniques provide promising new approaches (Nair et al. 2008; Welch et al. 2008; Lawton et al. 2010; Ray et al. 2011). Bubb et al. (2004) estimated that 2.5% of all tropical forests are cloud forests, with the lowest percentage in the Americas (1.2%) followed by Africa (1.4%) and Asia having the highest percentage (6.6%).

Owing to adaptation to regular cloud water interception, TMCF species are vulnerable to droughtlike conditions. Epiphytes, which grow on other plants in the TMCF and derive their moisture from the air, are a defining characteristic of cloud forests, where a quarter of all plants may be composed of various species of epiphytes (Foster 2001). Epiphytes are especially vulnerable to changes in regular cloud water immersion since they can only access intercepted water through organs dedicated to uptake of water deposited on them. Short intense pulses of rain events are thus relatively of little use to epiphytes. However, in many TMCFs, a significant proportion of the water input could be from continuous drizzle that keeps the organs for water uptake, such as roots, wet. Persistent fogginess also has led to specialist anuran and avian species that are adapted to specific altitudes corresponding to cloud frequency of immersion.

5.05.2 Stability of Tropical Montane Cloud Forests

The pressure to feed a growing and wealthier global population and grow biofuel crops has resulted in a net increase of the world's croplands and pastures by 154 million hectares between 1985 and 2005, which included significant expansions in the tropics and losses in the higher latitudes (Foley et al. 2011). It is estimated that 80% of new tropical croplands are from the conversion of forests (Gibbs et al. 2010). TMCFs are clearly threatened from these direct conversions into agricultural and pastoral lands and other developmental activities such as road constructions, building of dams and reservoirs, and mining activity (Ray et al. 2011). However, even when TMCFs are protected, they are affected indirectly by global, regional, and local processes that change the very critical 'regular immersion in clouds' process via changing the upper and lower bounds of clouds, cloud thickness, cloud cover and its frequency, cloud water content, and temperature changes.

5.05.2.1 Impacts of Global Changes

Changes in global scale processes impact TMCFs because the global scale atmospheric circulation of the Hadley cells determines the altitude of the trade wind inversion layer that in turn marks the upper bound of cloud top heights in the tropics.

BEFORE LOWLAND DEFORESTATION
(a)
Regular immersion in clouds: TMCF
Cloud base heights
Orographic uplift
Prevailing winds
Evaporation
Evapotranspiration
AFTER LOWLAND DEFORESTATION — REDUCED LOWLAND EVAPOTRANSPIRATION
TMCF regular immersion stopped/reduced — fewer and thinner clouds
(b)
Cloud base heights shifted upward
Orographic uplift
Prevailing winds
Evaporation
Deforestation - Transpiration stopped
AFTER LOWLAND DEFORESTATION — INCREASED EVAPOTRANSPIRATION
TMCF regular immersion increased
(c)
Cloud base heights shifted down
Orographic uplift
Prevailing winds
Evaporation
Deforestation - Evaporation increased from wetland

Figure 2 Effects of lowland land-use change on TMCF. (a) Current conditions. (b) Lowland deforestation reduces evapotranspiration and pushes cloud base heights upward. (c) Lowland deforestation increases evaporation from wetlands and lowers cloud base heights.

The trade wind inversion layer in turn is due to the descending branch of the Hadley cells and compression and warming of the air (Bruijnzeel et al. 2011). The altitude at which the orographically forced trade winds begin condensing clouds on the other hand determines the cloud base heights and thus the lower bound of the TMCF. The movement of the Intertropical Convergence Zone (ITCZ) also determines the timing and length of the wet season over the TMCF.

During the last glacial maximum, the drastically altered global conditions of temperature and precipitation influenced the spatial and altitudinal distribution of TMCFs. Lake pollen records from Andean TMCFs during the ice ages and modeling results show downslope expansion of TMCF species during the conditions of reduced temperature and wetter conditions that existed and consequently lowered cloud bases (Still et al. 1999; Urrego et al. 2005). Lowering of cloud bases allowed the TMCF

Table 1 Principle hydrometeorological and vegetation characteristics of TMCFs

Climate	*Vegetation*	*Productivity*	*Water balance*
High cloud frequency	High endemism	Low photosynthesis rates	Additional water input from horizontal precipitation
High relative humidity	High proportion of epiphytes	Low net primary productivity	Low transpiration and physical evaporation
Low irradiance	Stunted trees with small thick and hard leaves		Streamflow/incident rainfall very high

Adapted from Foster, P., 2001: The potential negative impacts of global climate change on tropical montane cloud forests. *Earth-Sci. Rev.*, **55,** 73–106.

species to colonize the lower elevations. Other studies, however, from Andean TMCFs suggest that during the ice ages aridity increased and fragmented the TMCF (e.g., Mourguiart and Ledru 2003). Clearly, global climate has a profound impact on TMCF spatial and altitudinal distributions.

Looking forward, atmospheric carbon dioxide has continued to increase, reaching a globally averaged concentration of 387.2 ppm at the end of 2009 (Friedlingstein et al. 2010). The technological advance required to stabilize greenhouse gas emissions, however, could be unachievable (Pielke et al. 2008), and emissions of carbon dioxide and other greenhouse gases are expected to continue; global climatic changes are occurring via altering the radiative balance of the earth's ocean–atmosphere system. Future globally averaged warmer conditions at the surface could result from these elevated greenhouse gases, which would increase evaporation from the water bodies that supply moisture leading to more cloudiness. However, at the same time, the condensation level for clouds could increase because of the warmer air thereby reducing cloud cover and the frequency with which cloud immersion occurs at the vegetation level (Still et al. 1999). It is not clear which process would dominate: more humidity and lowered cloud bases or more humidity but higher cloud bases due to warmer air masses at each TMCF site. Nor is there certainty of global climate changes being felt at each TMCF site. However, if the current regime of cloudiness and temperature changes for any reason, it could lead to the shifting of the current species composition, favoring those that are more adapted to the new conditions and extinction of others. Lack of cloudiness, for example, has been implicated in the outbreak of fungal diseases and species extinction of endemic TMCF fauna (e.g., Pounds et al. 2006).

Unfortunately, future cloud immersion is nearly impossible to predict at the individual TMCF locations, and studies that predict future conditions can only indirectly estimate the cloud immersion process via changes in other variables such as relative humidity (Still et al. 1999). This is because of multiple reasons: global climate models have coarse resolutions with each climate model grid cell representing areas of more than 1° of latitude–longitude, whereas TMCFs generally occur only as narrow altitudinal belts of less than a degree of latitude–longitude. Moreover, not only do TMCF belts occur as subgrid-scale regions within global climate model grid cells but the global climate models also parameterize subgrid-scale phenomena such as smaller scale clouds that are primarily the ones that bathe TMCF (Lawton et al. 2001). This means that even if global climate models could accurately predict the future climate, future cloud conditions at the vegetation level of TMCFs cannot be directly determined from global climate model simulations. While regional-scale dynamic downscaling from global model forecasts could provide future cloud frequency at the TMCF resolution, it is now quite clear that regional-scale downscaling is unable, at present, to add any value beyond what is already available via historical analyses, recent paleohistory, and worst case sequence of observed weather (Pielke and Wilby 2012). Under such conditions, a bottom–up assessment of historical regional processes that impact TMCF stability is more useful in understanding the indirect hydrometeorological threats to TMCFs. In order to make this assessment, what do past observations and modeling at TMCF sites tell us about their hydrometeorological vulnerability?

5.05.2.2 Impacts of Regional Changes

Modeling and observational studies show that regional land-use change could either raise or lower the altitudes of cloud formation, i.e., cloud base heights, but the magnitude of the impact is highly site specific. Generally, if the air column gets increasingly warmer and drier while traversing the landscape from the moisture sources before being forced to rise orographically, the altitude at which clouds form (cloud base height) also gets raised (Figure 2(b)). Not only the cloud base heights but also the thickness of clouds, cloud water content, and cloud immersion frequency could get reduced, thereby changing the hydrometeorological environment of the TMCF and subsequently its ecology, irreversibly. The amount by which the clouds are impacted differs based on the amount of upwind deforestation, new land use, and sea surface temperature changes. Inland cloud forests like those of southern Mexico and Costa Rica may be profoundly influenced by regional deforestation (Lawton et al. 2001). Multiple numerical modeling simulations from the Monteverde TMCF of Costa Rica (Nair et al. 2003; Ray et al. 2006) show how deforestation reduces cloud cover at the TMCF vegetation level.

Originally, tropical moist and wet forests covered most of the Costa Rican lowlands. However, by 1992, deforestation had reduced the forest cover in the lowlands to only 18% of the original forest cover (Veldkamp et al. 1992; Ray et al. 2006). Deforestation converted the forest trees that have a deeper root system into the shallower rooted agriculture (pasture grasses and seasonal agricultural crops have shallower roots, although tree plantation agriculture could have deeper roots). Field observations suggest that trees have access to water stored in deeper soil layers unlike cropland species (Ray et al. 2006). Studies from eastern Amazonia have also shown that up to 75% of all the water extracted during the dry season originates from soil layers below 2 m, which only trees can access (Nepstad et al. 1994). Thus, as the dry season progresses in Costa Rica's lowlands, evapotranspiration reduces, but because of conversion to cropland it now reduces drastically. This is affecting the cloud cover.

Nair et al. (2003) noted that patterns of cloud formation over the forested lowland regions in Costa Rica exhibited linear organization, but over the deforested areas the convection was unorganized. According to them, organized convection over forested lowland areas was indicative of reduced sensible heat fluxes over forests compared to deforested areas. Souza et al. (2000) via measurements of dry-season surface energy fluxes over paired forested–deforested sites in Amazonia showed a pattern similar to that found by Nair et al. (2003) for Costa Rica. The mechanism is explained in the extensively validated modeling study of Ray et al. (2006). The trade winds that blow over the now extensively deforested Atlantic lowlands of Costa Rica during the dry season encounter drier and warmer air due to the reduced evapotranspiration. Via turbulent mixing with this drier and warmer air the trade winds get drier and warmer (Figure 2(b)). It takes the trade winds around 5–10 h to traverse the extensively deforested Atlantic lowland areas of Costa Rica when this mixing process occurs (Lawton et al. 2001). If the lowlands were forested instead, it is very likely that transpiration would be higher because of trees accessing deeper soil moisture and thus the trade winds would have mixed with cooler and moister air. This in turn would dry and warm the trade winds comparatively less than what happens currently (**Figure 2(b)**). When these modified air masses from the lowlands now rise up orographically, the altitude at which water vapor begins to condense into cloud droplets is higher; in other words, the cloud base heights have been raised because of the extensive deforestation of the lowlands. Ray et al. (2006) estimate that this impact is greatest in the afternoon hours and has already reduced the areal coverage of cloud immersion by 5–13% because of the ~75-m rise in cloud base heights. They estimate that further lowland deforestation could reduce the spatial extent of cloud immersion by another 15% via another ~125-m rise in cloud base heights.

There are similar bottom–up evidences from other sites as well. Barradas et al. (2010) show that the widespread conversion of cloud-affected montane forests to agriculture and pastures in central Veracruz, eastern Mexico, is affecting the climate. There is an observable altitudinal shift in dry-season precipitation (notably in February), and overall fog frequency has also reduced. Ray et al. (2011) have also shown that if the lowland areas of the Western Ghats in southwest India are further deforested then the cloud base heights would increase in the dry season. This is similar to the mechanism reported from Costa Rica. However, unlike in Costa Rica where precipitation is also expected to reduce with further deforestation (Ray et al. 2010), over the Western Ghats precipitation could contrarily increase in the dry season, although cloud immersion reduces. On the other hand, coastal forests like those of some Caribbean islands (e.g., the Luquillo forest of Puerto Rico) may have too little upwind lowland to experience any lowland deforestation impacts (Lawton et al. 2001). While this may be true for many other coastal TMCFs, Van der Molen et al. (2006, 2010) have suggested a different mechanism and found decreases in cloud base heights and precipitation with deforestation (**Figure 2(c)**). On the other hand, using historical model simulations, Comarazamy and González (2011) have implicated climatic change as impacting the cloud base heights and precipitation in Puerto Rico's TMCFs.

While the studies of Van der Molen et al. (2006, 2010) and Comarazamy and González (2011) may disagree on the exact mechanism that lowered cloud base heights and reduced precipitation, they were both also partly conducted because water supply in Puerto Rico decreased in the 1990s and led to water rationing, affecting millions (Van der Molen et al. 2010). According to Van der Molen et al. (2006, 2010), deforestation reduced the sensible heat flux because the pastures of Puerto Rico that replaced the forests were well-watered long grasses. Thus, under clear and calm conditions, when the sea breeze dominates the trade wind flow, reduction in sensible heat flux from deforestation reduced the strength of the sea breeze, resulting in lower cloud base heights, but the reduced uplift also lowered the precipitation. Comarazamy and González (2011), however, found a global warming signal driving the reductions in precipitation in Puerto Rico. According to them, between 1955 and 2000 the lower atmospheric temperature has increased between 1.0 and 1.8 °C over the Caribbean region but much higher toward the North Atlantic. This has created a pressure difference between the two regions that has intensified and also changed the flow direction of the trade winds in such a way that the axis of the orographic uplift has itself shifted. The new flow direction has reduced orographic uplift over the TMCF sites and reduced precipitation, although higher humidity has increased cloud thickness, thus appearing as lowering of the cloud bases.

Clearly, there is a lot of variation in the exact mechanism even at a site, and at different times different mechanisms may dominate, but similar bottom–up investigations are urgently required elsewhere to determine the most dominant process and the conditions under which they would dominate. One of the key determining factors for the cloud base height and its prediction at each TMCF site is measuring the Bowen ratio – the ratio of sensible heat flux to latent heat flux. As evapotranspiration reduces, radiative balance is achieved via increased sensible heat flux, and the Bowen ratio increases. A higher sensible heat flux triggers stronger updrafts and higher cloud base heights. Thus, cloud base heights are lowered with lower Bowen ratios (Foster 2001). Historical global climate signals such as those of Comarazamy and González (2011) provide additional layers of information. For example, under calmer conditions, local processes could dominate, and clearly, the nature of the lowland land use would then impact the TMCF. In other places such as Costa Rica, even when the trade winds dominate, the nature of lowland land use would impact the TMCF, as the trade winds mix for long periods with the air column over the lowlands during which they can be significantly modified prior to orographic uplift. Unfortunately, while it is quite clear that similar bottom–up observations and modeling exercises are required, the continent with the largest proportion of TMCF, i.e., Asia, is the least studied and the Americas with the least proportion of tropical forests as TMCFs are the most studied.

In general, at each TMCF site, the hydrometeorological conditions are being simultaneously impacted from global, regional, and local factors, but one or more of these generally dominate. Moreover, the occurrence of montane cloud forests and the thickness of the cloud forest belt itself are governed by the altitude of persistent cloud condensation, which needs to be urgently determined to establish a baseline against which changes could be measured. What is, however, clear is that with increasing distance from the ocean, air tends to be drier and therefore requires lower temperatures and higher elevations to reach its condensation point. Consequently, the associated cloud base and TMCF vegetation will occur at higher elevations farther from the oceans. Likewise, at given moisture content, the condensation point is reached more rapidly by cooler air than by warmer air. Thus, at greater distances from the equator, the average temperature, and therefore the altitude at which condensation and TMCFs occur, will be lower. If land-use change reduces evapotranspiration into the air masses as they travel from the oceans to the mountains then the cloud bases will rise and cloud forests at lower elevations will become unstable and vice versa. If global climate changes the direction of flow, then cloud formation will change and TMCFs will become unstable.

5.05.3 Bottom–Up Solutions

Currently, the most serious challenge being faced by TMCFs is from economic activities that are directly destroying

TMCFs – construction of roads and other infrastructure, timber and mineral extraction, telecommunication facilities, tourist development (including golf courses), hydropower production, illegal plant collection, excessive and inappropriate tourism, and steady encroachment of agriculture (Kumaran et al. 2010; Meyer 2010; Owiunji and Plumptre 2010; Ray et al. 2011). The loss of cloud forests can even induce fires and destroy other areas of the cloud forest. Other destructive activities include grazing or trampling by feral ungulates and invasion by alien plant species (Meyer 2010). Some areas that lost TMCFs are now being allowed to recover because of changed political, economic, and social drivers (Aide et al. 2010). TMCF recoveries are, however, hampered from competition with invasive grasses and ferns and poor seed dispersal (Aide et al. 2010). One of the most cost-effective ways to accelerate the recovery of TMCFs is to promote the establishment of shrubs, which helps to shade out invasive grasses and ferns and create more appropriate conditions for seedling growth. This strategy reduces the competition faced by the original TMCF plant species, but clearly, not all TMCF species will recover successfully. Thus, planting will also be required to recover a species composition similar to the intact forest because most forest species are rarely dispersed far from forest stands (Aide et al. 2010).

Where modeling studies have already shown that conversion of lowlands to shallow-rooted agriculture impacts TMCF cloud immersion, deforestation should be immediately stopped to prevent any further reduction in the frequency with which cloud immersion occurs. In areas where no assessment has yet been done, modelers should make extra efforts because the rates of lowland deforestation is very high in the tropics and is expected to continue in the near future. Historical simulations such as those of Comarazamy and González (2011) should be done to determine climate impacts. A global effort with focused local action in which researchers, governmental agencies, local authorities, NGOs, private enterprises, and civil society all work together is urgently required (Bruijnzeel et al. 2010).

Finally, relevance to the conservation of biodiversity is the most common justification for conducting research not just about TMCFs but also in all biology-related tropical research. A study by Pitman et al. (2007) shows that there is a distinct disconnect between 'foreign researchers' and the perceived beneficiaries of the research. Foreign authors tend to focus on basic science that the on-the-ground beneficiary cannot understand; publish their results in very expensive academic journals in which they cite each other but that the beneficiary invariably cannot access; publish in English, which most of the beneficiaries cannot read, and have few explicit conservation recommendations. On the other hand, 'gray literature,' written mostly by on-the-ground practitioners of conservation in the tropics is related to management, not digitally available, non-peer reviewed, and in a non-English language that 'foreign researchers' cannot access. For the bottom–up process to really succeed for TMCF conservation "scientists in the tropics, regardless of their nationality" need "to examine and reexamine the practical connections between the work they do and the work done by those who manage tropical lands. For scientists whose funding derives from grant proposals that invoke the critical environmental situation in the tropics, this is practically an ethical obligation" (Pitman et al. 2007).

5.06.1 Introduction

Urban water infrastructure systems provide for water supply, stormwater management, and wastewater collection and disposal (Figure 1). In the United States and most developed nations, these systems comprise extensive networks of physical infrastructure interconnected with natural waterways and are managed by a collection of large centralized institutional entities defined according to political and jurisdictional boundaries instead of watershed boundaries. Water supply systems begin at a source of water (e.g., lake, river, stream, spring, ocean, aquifer, reservoir) followed by extraction or diversion into an infrastructure network that treats, stores, and distributes the water to users. Stormwater management systems direct surface runoff into a connected network of gutters, channels, pipes, ponds, and other components. Typically, stormwater is infiltrated, retained in control structures, or detained and directed untreated into streams, rivers, lakes, and coastal waters. Wastewater, in general, is managed using two approaches. In most areas of rural and low-density development, wastewater is disposed of using septic systems; in denser metropolitan areas, wastewater is collected in sewer networks, conveyed to treatment facilities, and treated prior to discharge. Each of these urban water infrastructure systems is vulnerable (i.e., may be adversely affected) to climate, land use change, population growth, socioeconomic development, increasing per capita water demand, aging and deteriorating infrastructure components, regulations, and behaviors (Figure 1).

The impact of urbanization and population growth are the predominant, and in most cases, only factors considered in planning and design of urban water infrastructure systems. Changes in landscapes to urban or new urban uses may modify land surface, building, and infrastructure characteristics leading to changes in water use, stormwater runoff, and wastewater generation rates. For example, the stormwater system becomes vulnerable when the removal of natural vegetation and trees during urbanization reduces interception capacity, thereby increasing the amount of rainfall reaching the ground surface. Moreover, the compaction of soil during construction (Pitt et al. 1999) and the introduction of impervious surfaces (Schueler 1994) reduce depression storage, infiltration, and groundwater recharge. These altered surface characteristics, combined with the introduction of efficient drainage systems, increase the drainage density of urban catchments, which decreases the travel time of overland flow to the drainage system and leads to flashier and higher-volume hydrologic responses and altered streamflow (Booth and Jackson 1997).

Population growth is another key stressor of urban water infrastructure systems contributing to vulnerability. Population growth is not only linked to changes in runoff but also causes larger scale increases in water demand and wastewater generation. It is the single most important factor used for water supply planning and is one that comes with substantial uncertainty. Projecting an estimated future metropolitan population is challenging in itself but is further complicated when projecting the impacts on water demand, surface runoff, and wastewater generation, thereby limiting the ability of utilities to precisely plan future system needs.

Another vulnerability of urban water infrastructure systems is aging and degradation of components. This vulnerability has been highlighted in numerous reports indicating the state of the infrastructure today and the projected state in the near future. Water losses of 10–20% are considered normal, and losses as much as 50% have been found in cities in the United States (US EPA 2009). Nationally, leaking pipes lose an estimated 7 billion gallons of drinking water each day (http://www.infrastructurereportcard.org/fact-sheet/drinking-water). Without proper corrective actions, this system vulnerability is expected to intensify and expand in the future.

The relative importance of each vulnerability-related stressor on future urban water infrastructure resiliency and sustainability is dependent on local conditions and future

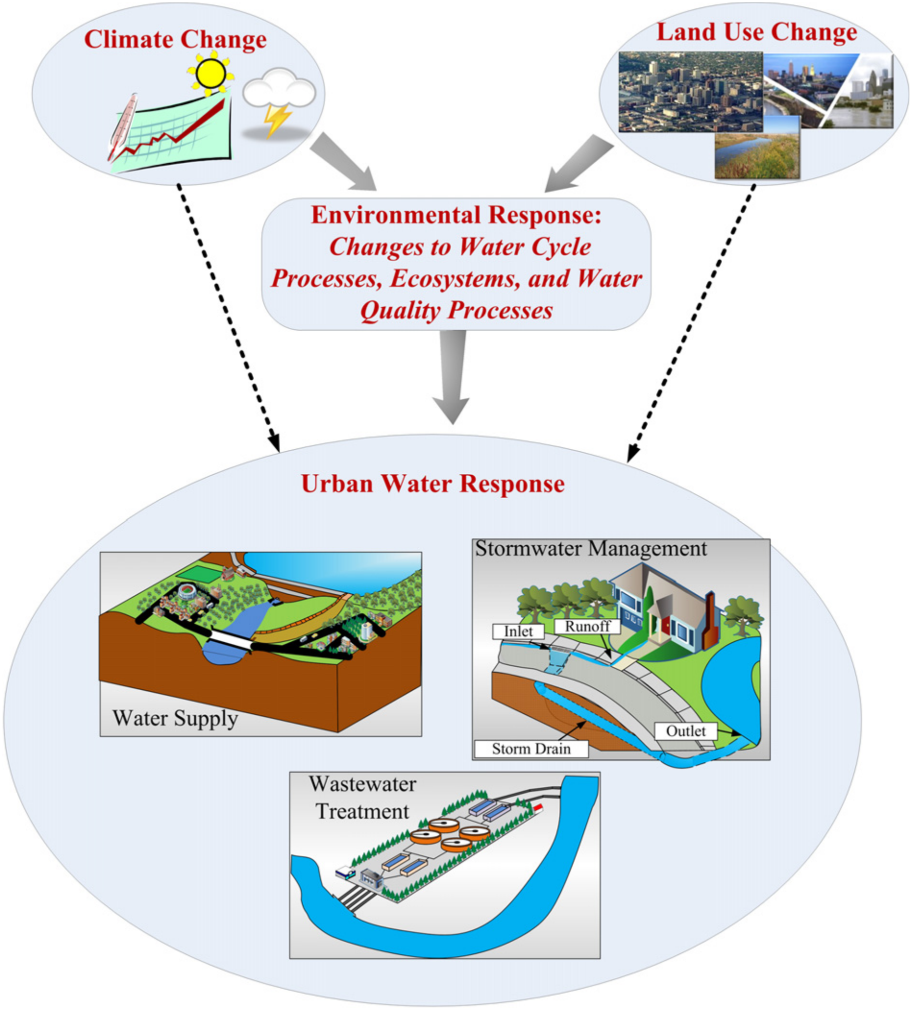

Figure 1 Pressures (e.g., climate, land use) impact environmental systems that in turn elicit a response within urban water infrastructure systems. Note: Possible feedbacks such as from urban water systems (e.g., reservoirs) and urbanization (e.g., urban heat island effect) to local climate are expected but not shown here.

trajectory of the influencing factors. A comprehensive water utility vulnerability assessment would address all of these factors and determine when and how to address them in a long-term adaptation plan. In-depth coverage of all of the factors is beyond the scope of this chapter. Rather, for consistency with the theme of the volume, the focus of this chapter is specifically on the vulnerabilities and adaptation measures to climate and a few key drivers of the water cycle.

Climate variability is generally defined as the variation in climate over space and time due to natural (e.g., fluctuations in ocean circulations, volcanic eruption) or anthropogenic (e.g., increased greenhouse gas emissions) influences (IPCC 2007a). Both natural and human-induced variability are relevant for this chapter because both affect the water cycle in similar ways that affect urban water infrastructure systems. Natural climate variability has been observed throughout history. Recently, the Intergovernmental Panel on Climate Change (IPCC) concluded that trends in global temperature over the past century could not be explained solely on the basis of the inherent variability of the climate system (IPCC 2001). Their assertion was that human-induced climate variability was also occurring. Natural climate variability is known to alter the water cycle (e.g., extended periods of reduced precipitation leading to drought), and human-induced climate effects would also have local and regional impacts on the water cycle, including altered evapotranspiration (ET), soil moisture, precipitation, groundwater recharge, and runoff (Allen and Ingram 2002; Milly et al. 2005; Schneider et al. 2007; Trapp et al. 2007).

Climate vulnerability of urban water infrastructure systems is defined as the state of being exposed to consequences and adversely affected from climate pressures on the water cycle, especially changes in precipitation intensity and frequency of extreme events, leading to a range of possible impacts that include increased runoff, reduced recharge, and higher flooding potential (IPCC 2007b). The resulting impacts on urban water infrastructure systems include physical damage, system failure, risk to population, and financial loss. The infrastructure components and entire systems are sensitive to resource changes on short (days), medium (season), and long (multiple decades) timescales.

Vulnerabilities to urban water infrastructure systems can be reduced by taking actions to mitigate or adapt to the human-induced and natural climate variability impacts. Adaptation is adjusting the built or natural system in response to climate variability impacts to reduce harm (Hamin and Gurran 2009). This chapter focuses on adaptation of urban water infrastructure systems; however, it is important to remember that mitigation and adaptation are interrelated and can either be a detriment or synergistic to one another (Buob and Stephan 2011).

The goals of this chapter are to summarize climate vulnerabilities and adaptation strategies of urban water infrastructure systems, identify climate vulnerabilities and adaptation potential of new green infrastructure and decentralization approaches, and highlight the importance of the interdependency of urban water infrastructure and energy requirements in relation to climate vulnerabilities and adaptation. The next section presents an overview of climate vulnerabilities and adaptation strategies of the three urban water infrastructure systems: water supply, stormwater management, and wastewater collection. Section 5.06.3 Toward Sustainable Urban Water Systems explores the climate vulnerabilities and adaptation potential of the new approaches of green infrastructure and decentralization, and identifies potential implications of climate vulnerabilities of urban water infrastructure systems for energy requirements.

5.06.2 Conventional Urban Water Infrastructure Systems

The pressures of climate on urban water infrastructure systems may influence their ability to meet former safety factors built into their designs for future demand requirements. Urban water systems are designed with a specified performance level, sometimes based on an adopted risk. For example, stormwater drainage systems are designed to infiltrate, convey, or capture a design rainfall event that historically has occurred on average once over a specified duration. Often the once-in-10-year event is selected for design of storm drainage networks with less frequent events (e.g., a once-in-50-year event) used for culverts, bridges, and other higher risk components. Water supply planning is based on population projections and assumed per capita or detailed demand estimates. The primary problem with past designs is that the basis of design used by engineers is becoming inadequate and may continue to be so as climate extremes intensify (Purkey et al. 2007). For example, water demands may increase in some places, and bridges, levees, and other water infrastructure designed to withstand the 100-year recurrence interval storm event may face more frequent high-intensity events. Indeed, these projected climate pressures have been observed in recent climate trends (Mount and Twiss 2005; Vicuña et al. 2006) as well as hazards and impact events. Additionally, other such climate-related pressures, as altered water cycle processes, change to air and water temperatures, and sea level rise (SLR) would affect urban water systems (Walsh et al. 2004; Barnett et al. 2005; IUCN 2008).

The general methodology of assessing climate vulnerabilities of urban water infrastructure systems can be broadly classified as 'top–down' or 'bottom–up' (Miller and Yates 2006; Usher 2010; Vogel and Smith 2010). The top–down approach refers to methods representing climate variability and change in the form of scenarios (e.g., increased/decreased precipitation, higher precipitation intensity, increased frequency of extreme events) using one or more of (but not limited to) the following types: (a) extrapolating from historical and paleoclimate precipitation records (Denault et al. 2007; Rosenberg et al. 2010), (b) synthesizing climate impacts using downscaled regional or global climate model outputs (for impacts on hydrology, see Maurer 2007; Beyene et al. 2010; Elsner et al. 2010; Maurer et al. 2010; for impacts on stormwater, see Semadeni-Davies et al. 2008; He et al. 2011), (c) simulating ensemble scenarios based on downscaled general circulation model (GCM) outputs (Rosenberg et al. 2010; for SLR, see Purvis et al. 2008), and (d) synthesis from literature reviews. Top–down approaches are model driven, as they may include application of GCMs and the integration of downscaled outputs with hydrologic or system models (Vogel and Smith 2010). The most common approach of top–down type methodologies for climate impacts is to use downscaled climate projections generated from GCM output in conjunction with hydrologic and/or water resource system models.

Bottom–up approaches, on the other hand, focus on local scales (e.g., urban drainage system of a city) and typically involve qualitative and quantitative assessment of system components to identify vulnerabilities. Most often, bottom–up approaches involve individuals with extensive knowledge of the natural and built systems that are being assessed. A usual process involves defining thresholds and performance criteria for the water infrastructure system components that represent the normal of expected operation without climate variation or change conditions, establishing climate variables of interest, determining system response to changes in important climate variables, and then developing and testing adaptation strategies (Freas et al. 2008). Alternatively, scenarios representing pressures on the system (e.g., altered precipitation intensity) that may or may not be predicted by downscaling analyses of model-projected climate have also been employed in sensitivity analyses that represent a hybrid of top–down and bottom–up approaches.

The focus on systems and components in a bottom–up approach permits a more comprehensive vulnerability assessment that extends beyond climate variability and change to include other key pressures (e.g., land use change, population growth, aging infrastructure, altered demands and water quality, socioeconomic changes) as well as the synergistic impacts of multiple pressures and of possible climatic conditions not included in the downscaled scenarios (Pielke et al. in press). The relative importance of climate vs. urban growth and other factors is dependent on site and conditions and is influenced by the scenario and modeling assumptions and local characteristics (Praskievicz and Chang 2009), which leads to the need for a bottom–up approach.

The use of the top–down approach is also limited by the uncertainty of data and the models used to drive the analysis. Uncertainty exists in projecting climate variability and change into the future and downscaling to the level necessary for water infrastructure assessment. Downscaling is especially

Table 1 Urban water infrastructure system pressure–response matrix

	Infrastructure impact/response		
Pressure (water cycle change)	*Water supply*[a]	*Stormwater*	*Wastewater*
Decreased precipitation	▼ Decreased water yield and recharge	▲▼ Decreased runoff volume; increased recurrence intervals[b,c]; increased pollutant concentrations	▲▼ Fewer CSO events; decreased streamflow leading to lower assimilative capacity
Increased precipitation	▲ Increased water yield and recharge	▼ Increased runoff volume[d]; increased peak flow; decreased recurrence intervals[b,c]; increased waterway erosion and flood risk; increased water turbidity[d]	▲▼ More CSO events; increased streamflow leading to greater assimilative capacity
Altered precipitation timing – Seasonal and interannual	▼ Water infrastructure designed based on supply–demand timing – negative impact on operations[e]	○ No significant impact	○ No significant impact
Increased precipitation intensity	▼ Increased flood risk to water supply infrastructure; decreased infiltration; increased contamination of water sources from runoff pollution[f]	▼ Decreased annual recurrence intervals[b]; increased peak flow, runoff,[d] erosion, flood risk, and turbidity[d]	▼ More CSO events; increased WWTP loading
Decreased precipitation intensity	○ No significant impact	▲ Decreased runoff; decreased pollutant loading	▲ Fewer CSO events
Increased ET	▼ Increased losses from reservoirs; increased salinization of water sources; decreased surface water and groundwater availability	▲ Increased removal of stored runoff in detention and retention basins[g]	○ No significant impact
Increased snow pack	▲ Increased water yield	▼ Increased melt runoff and flood risk	▲ Increased dilution of contaminant loads
Decreased snow pack	▼ Decreased water yield	▲ Decreased melt runoff and flood risk	▼ Decreased dilution of concentration loads
Earlier snowmelt	▼ Change to supply–demand timing challenges operations	○ No significant impact	○ No significant impact
Later snowmelt	▼ Change to supply–demand timing challenges operations	○ No significant impact	○ No significant impact

Increased streamflow	▲ Increased surface water availability	▲▼ Increased flood risk; increased dilution capacity	▲▼ Increased dilution of CSO loads; increased flood risk at outfall and backup into collection system
Decreased streamflow	▼ Decreased surface water availability	▲▼ Decreased flood risk; decreased dilution capacity	▲▼ Decreased dilution of CSO loads; decreased flood risk at outfall and backup into collection system
Raised groundwater table	○ No significant impact	▼ Waterlogging of green infrastructure[h]	▼ Increased exposure of sewer lines to groundwater – increased infiltration and inflow and contamination of groundwater
Lowered groundwater table	▼ Wells may run dry; increased pumping costs	○ No significant impact	○ No significant impact
Improved surface water quality	▲ Decreased treatment costs	▲ Decreased impact of pollutant loading	▲ Decreased impact of CSO loading
Degraded surface water quality	▼ Increased treatment costs	▼ Increased impact of pollution loading	▼ Increased impact of CSO pollution loading
Increased surface water temperature	▲▼ Decreased dissolved oxygen (DO), accelerated organic growth, algal blooms, altered chemical reactions, higher or lower treatment costs (depends on treatment process)	▼ Decreased DO affects certain aquatic species[i]; increased impact of pollution loading	▼ Increased impact of CSO pollution loading; altered discharge conditions for WWTPs (e.g., permits more restrictive)
Decreased surface water temperature	▲▼ Increased DO, decreased organic matter, altered chemical reactions; higher or lower treatment costs (depends on treatment process)	▲ Increased DO levels – reduced impact of pollution loading	▲ Decreased impact of CSO pollution loading; altered discharge conditions for WWTPs (i.e., permits less restrictive)
Improved groundwater quality	▲ Decreased treatment costs	○ No significant impact	○ No significant impact
Degraded groundwater quality	▼ Increased treatment costs	○ No significant impact	○ No significant impact
Sea level rise	▼ Saltwater intrusion into wells	▼ Increased flood risk[j]	▼ Increased flood risk for treatment facilities; outfall backup due to impacted hydraulics

Note: A negative response indicated by a downward pointing arrow (▼) means the pressure is usually anticipated to have a negative effect. A typically anticipated positive response is symbolized by an upward pointing arrow (▲). A neutral response is symbolized by an open circle (○). If both a positive and negative are shown, it may have positive or negative depending on local conditions. A vulnerability may be likely if the response is negative.

problematic when trying to represent the temporal and spatial resolution of precipitation essential for water infrastructure analysis (Willems et al. 2011). Given the longevity of urban infrastructure, it is critical that decision making concerning water systems does not reinforce negative feedback in any part of the process (Lindley et al. 2006). In response to the advantages and disadvantages of both approaches, some water utilities have incorporated elements of both the top–down and bottom–up approaches into their assessment (US EPA 2010a).

Climate vulnerabilities to water supply, stormwater drainage, and wastewater collection systems have typically been assessed independently. Cities are responding to model-projected climate impacts by conducting vulnerability analyses for their water infrastructure systems and in some cases are embracing Integrated Resource Planning (IRP), which analyzes the impacts to all phases of the water supply and consumption cycle for the given system (Cromwell et al. 2007). In the United States, generalities of IPCC model-predicted climate impacts for future emission scenarios include the assumptions that coastal cities would be vulnerable to SLR and that Midwest and East Coast cities would be vulnerable to more intense storms. The West would be especially vulnerable to climate variation that could lead to water supply shortages and changes in snowmelt runoff timing, quality, and quantity. A recent report by the Natural Resources Defense Council (NRDC) highlights water-related climate risks in 12 US cities and describes the measured cities are taking to become more resilient (Dorfman et al. 2011).

Vulnerabilities of urban water systems vary in different countries based on expectations for reliability. This chapter focuses on the expected system reliability in the United States. Vulnerabilities can include environmental, social, political, economic, and security externalities, but this chapter focuses on climate. Generally, climate vulnerabilities of urban water systems fall into three categories: increased quantity (increased intensity and frequency of extreme events, SLR), decreased quantity (decreased water availability due to reduced precipitation, altered hydrologic response, and increased demand), and decreased quality. Each of these is considered in this chapter. The following subsections describe climate vulnerabilities and adaptation approaches of conventional (meaning those that are currently in widespread use in the United States) water supply, stormwater management, and wastewater collection systems.

5.06.2.1 Water Supply

Urban water supply infrastructure includes surface water diversions, wells, pumps, transmission pipes and canals, treatment and storage facilities, and distribution network elements. Sources include rivers, reservoirs, seawater, and groundwater. Climate variability leads to numerous physical changes to the water cycle that act as pressures to affect urban water infrastructure systems. Table 1 provides a comprehensive list of climate-related pressures on urban water infrastructure systems and indicates possible impacts and responses from the infrastructure systems.

As noted in Table 1, urban water supply has a propensity to be affected by pressures on both the supply and the demand sides, which exposes vulnerabilities. On the supply side, effects are anticipated regarding the quantity, timing, and quality of source water. On the demand side, effects are expected in use patterns in response to climate impacts. For example, alterations of temperature and relative humidity, growing season duration, and precipitation patterns may lead to changes in water demand for municipal landscape irrigation. IPCC model-based investigations of water supply impacts of climate predict reduced water availability and degraded quality (Gleick and Chalecki 1999; Gleick and Adams 2000).

Most studies of urban water supply system vulnerabilities to climate change are top–down as they have used scenarios from GCMs. In such a top–down approach, the climate change estimates of precipitation, temperature, and other meteorological parameters are used to drive a hydrologic model, which is then used to quantify changes in streamflow and reservoir water surface levels. A final stage of analysis that assesses impacts on municipal water supply systems is sometimes included (Wiley and Palmer 2008). The use of probability-based methods for assessing climate variability has also been employed and is used to provide risk-based outputs, including confidence levels (Maheepala and Perera 2003). However, application of probabilistic methods beyond research is limited, whereas the use of indicators defined specifically for climate impact assessment has proven worthwhile for addressing the problem quantitatively (Hurd et al. 1999).

In general, an altered hydrologic cycle from altered climate variability will result in modifications to the water yield (either surface water or groundwater resources) or alter the timing of the supply with respect to the demand (see, e.g., Barnett et al. 2005). The watersheds with the greatest vulnerability are those that are already stressed by existing conditions or face multiple stressors in addition to climate (Hurd et al. 1999). Vulnerability assessments carried out by water utilities have generally used external climate expertise for climate information and accounted for the uncertainty by employing a range of scenarios or models to test the robustness of the system to a subset of different possible future climate perturbations (US EPA 2010a).

Reservoirs are provided to equilibrate the timing of water supply, but the design and operation of the reservoir system may be vulnerable to climate. Studies of top–down model-predicted future climate impacts on water supply are often compounded by the added uncertainty of also projecting water demand. A study of reservoir storage capacity for the City of San Diego looked at both predictions of water demand and climate and determined that the addition of the human-induced climate forcings along with projected water demand would lead to greater costs for the city (O'Hara and Georgakakos 2006). Vano et al. (2010) studied the relative importance of population growth and model-predicted climate in the Puget Sound region.

Larger-scale impacts to water supply would occur from altered groundwater levels and SLR. Modified infiltration and recharge and increased withdrawals may lead to lowered groundwater levels. This would make existing pumping facilities ineffective or could lead to higher energy requirements for groundwater development (Larsen 2010).

Of all the climate effects on the water cycle listed in Table 1, SLR is the one that has gained the most consensus in terms of its response. SLR is predicted to occur with the claimed uncertainty mainly in the magnitude of the rise and the timing. Urban water infrastructure systems are vulnerable to SLR and the impacts may include saltwater intrusion in coastal wells.

Demand-side changes are also possible although not listed in Table 1. Climate-induced alterations of temperature and relative humidity, growing season duration, and precipitation patterns may lead to changes in water demand for municipal landscape irrigation and other outdoor uses. A study of water demand forecasts in three counties in Washington found the effects of the top–down predicted climate change, 50 years in the future, to be an average annual water demand increase of 5–12% (WSF 2009). However, projecting long-term changes to water demand are difficult since water demand generally increases with temperature and decreases with precipitation. Given the challenges of projecting demand-side changes, broader climate impact assessments of water supply infrastructure have been conducted within the analysis of the larger urban system impacts (e.g., for New York City, Rosenzweig et al. 2000).

Eight major water agencies in the United States formed the Water Utility Climate Alliance (WUCA) in February 2008 (WUCA 2011). Many water utilities now plan for and identify investments to mitigate and adapt their systems to climate variability and longer-term change based on tools including risk assessment and total water management (Freas et al. 2008). Effects on water utilities have been classified into several categories: water quantity, water quality, operational reliability, financial, and institutional (Water Research Foundation 2008; AWWA Climate Change Committee 2011). In general, adaptation objectives of water utilities are to diversify the water supply portfolio and seek low cost, 'no regrets' solutions (NDWAC 2010). No regrets adaptation strategies are those that "would generate net social and/or economic benefits irrespective of whether or not climate change occurs" (IPCC 2007c; Elliot et al. 2011). Costs to drinking water utilities in the United States for adaptation to possible climate conditions are estimated to be \$325–\$692 billion (CH2M Hill, AMWA, and NACWA 2009), although these costs are based primarily on 'hard-path' solutions.

Adaptation measures that are generally applied include conducting water resources planning using 'nonstationary' assumptions (Milly et al. 2008) and reducing demand. More detailed adaptation approaches and techniques are listed and described in Table 2 according to the pressure they are addressing. The most common structural adaptation measure typically considered is increasing storage capacity. Increasing storage is one of the 'no regrets' measures from the water supply perspective because it addresses a broad range of pressures related to climate variability and longer-term change, urbanization, and other factors. However, this route is expensive. Adjusting the operating plan of existing reservoirs has some potential benefits and is inexpensive, but increased storage is expected to have a greater impact across vulnerabilities. Research has shown that adding storage capacity to reservoirs will have larger benefits for adapting to increased demands vs. altered inflows and evaporation from climate.

It is important to note that the vulnerabilities and adaptation measures noted in Tables 1 and 2 assume that the paradigm for urban water management remains the same. However, alternative approaches to urban water management are being developed in response to wholesale changes in economy, energy, and urban development. Emerging changes to urban water infrastructure systems are highlighted in Section 5.06.3 of this chapter.

5.06.2.2 Stormwater Management and Flood Control

Stormwater management and flood control infrastructure may generally be classified (Gregory et al. 2005) as conveyance channels and conduits (e.g., streams, canals, ditches, culverts, pipes, streets), storage facilities (e.g., lakes, ponds, detention/retention basins), and other control structures (e.g., gates, locks, weirs, levees, berms, pump systems).

Climate vulnerabilities to stormwater and flood control infrastructure are related to (a) system design and (b) operation and maintenance (see Table 1). For design, engineering may have to consider the nonstationarity of historical precipitation used in the development of depth–duration–frequency curves and its impact on the selection of design storm magnitudes (NRC 2008; Rosenberg et al. 2010) in response to climate variability and longer-term change. From the operation and maintenance perspective, stormwater and floodplain managers may have to regularly monitor the system response to increased extreme events, high-intensity storms, and early spring flows. For example, increased erosion and sedimentation in urban water system streams and storm drains due to increased runoff would result in clogging of storm drains, leading to a backup of water and of culvert openings, backwater effects, and local flooding.

Climate pressures on urban drainage systems comprise (a) water quantity related impacts including increased runoff and flooding (Ashley et al. 2005; Milly et al. 2005), increased combined sewer overflow (CSO) occurrences (Liebl 2011), and increased erosion at sites with no drainage features and (b) water quality impacts from altered stormwater pollutant concentrations, increased erosion, increased turbidity, and elevated in-stream water temperatures (Debo and Reese 2003; Rosenberg et al. 2010; He et al. 2011). These effects of climate pressures vary with geographic region and level of urbanization. For example, Milly et al. (2005) presented climate model predictions of runoff increases of up to 40% by the year 2050 in the eastern equatorial Africa, high-latitude North America, and Eurasia, while parts of southern Africa, southern Europe, the Middle East, and the mid-latitude of North America were simulated to have runoff decreases of up to 30%. Dorfman et al. (2011) identified increased flooding as the most common climate risk in 12 US cities. Scientific studies that they reviewed indicated that rainfall intensity is forecast by the IPCC models to increase in many of their case study cities, leading to an increased incidence of flooding. This would in turn lead to an increased number of CSO events. The Great Lakes region, for example, is estimated to experience increased daily CSO discharges by up to two times a year, due to climate change according to US EPA (2008a).

Assuming, first, that current stormwater management practices continue unchanged into the future and, second, that a 30% shift in extreme precipitation quantiles would occur, it can be expected that quantity issues (e.g., flooding and combined sewer surcharging) would be twice as likely to occur

Table 2 Urban water infrastructure adaptation matrix

	Infrastructure adaptation		
Pressure (water cycle change)	*Water supply*	*Stormwater*	*Wastewater*
Decreased precipitation	$$ Reduce demand; create new water allocations; develop alternative sources and decentralize	$ Protect and reestablish wetlands to retain runoff and recharge groundwater[a]	○ Minimal adaptation necessary
Increased precipitation	○ Minimal adaptation necessary	$$$ Increase storage; install detention/retention facilities; improve channel stability; improve emergency response capacity; increase storm drain pipe size; install observational networks for flood forecasting[b]	$$$ Increase capacity for storage and treatment in combined sewer systems
Altered precipitation timing	$$$ Change reservoir operation; create new water allocation policy; reduce seasonal demand; increase storage capacity[c]	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Increased precipitation intensity	○ Minimal adaptation necessary	$$$ Increase storage; improve emergency response capacity; install observational networks for flood forecasting[b]	$$$ Increase capacity for storage, surge protection, and treatment in combined sewer systems
Decreased precipitation intensity	○ Minimal adaptation necessary	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Increased ET	$$ Alter storage infrastructure approach (e.g., aquifer storage and recovery)	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Increased snow pack	○ Minimal adaptation necessary	$$ Increase storage and detention/retention facilities; fortify channels for flood control	○ Minimal adaptation necessary
Decreased snow pack	$$$ Increase storage capacity; create new water allocation policy; develop alternative sources of water supply; reduce demand	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Earlier snowmelt	$$ Increase storage capacity; develop alternative sources of water supply; reduce or change timing of demand	$ Implement integrated stormwater/flood risk management studies[d]; improve emergency response capacity	○ Minimal adaptation necessary
Later snowmelt	○ Minimal adaptation necessary	○ Minimal adaptation necessary	○ Minimal adaptation necessary

Increased streamflow	○ Minimal adaptation necessary	$$ Implement integrated stormwater/flood risk management studies[d]; minimize impervious surfaces; encourage riparian buffer zones along waterways[a]; install observational networks for flood forecasting[b]	$ Elevate or protect WWTP discharge outlet location from backflow or flooding
Decreased streamflow	$$$ Modify intake structures; reduce demand; develop alternative sources of water supply	$$ Install stormwater quality control devices	$$ CSO discharges have greater harm – need to increase controls and/or treatment in Total Maximum Daily Load (TMDL) locations
Raised groundwater table	○ Minimal adaptation necessary	$$ Map hydric soils to select locations for new drainage designs; prevent stormwater leaks[e]	$$ Increased repair or replacement of wastewater mains
Lowered groundwater table	$$ Drill deeper wells; develop alternative sources	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Improved surface water quality	○ Minimal adaptation necessary	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Degraded surface water quality	$$$ Introduce new treatment; develop new sources; revise standards	$$ Disconnect stormwater inputs; educate homeowners, farmers[f,g]; install source control best management practices (BMP)[h]	$$ Depends on local and National Pollutant Discharge Elimination System (NPDES) permit conditions; CSO discharges have greater harm—need to increase controls and/or treatment in TMDL locations
Increased surface water temperature	○ Minimal adaptation necessary	$ LID or GI, in place of traditional detention/retention	○ Minimal adaptation necessary
Decreased surface water temperature	○ Minimal adaptation necessary	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Improved groundwater quality	○ Minimal adaptation necessary	○ Minimal adaptation necessary	○ Minimal adaptation necessary
Degraded groundwater quality	$$$ Introduce new treatment; develop new sources	$ Educate homeowners, farmers[f,g]	○ Minimal adaptation necessary
Sea level rise	$$$ Introduce new treatment; develop new sources	$$$ Install sea walls; install pumps; integrated coastal flood risk management[e,f]	$$$ Impacts outfalls – may require pumping; treatment facilities may need to be moved or protected from inundation

Note: Shown are possible adaptation measures for urban water infrastructure systems and the relative cost (○ indicates negligible cost; $ indicates low cost, $$ indicates moderate cost, and $$$ indicates high cost).

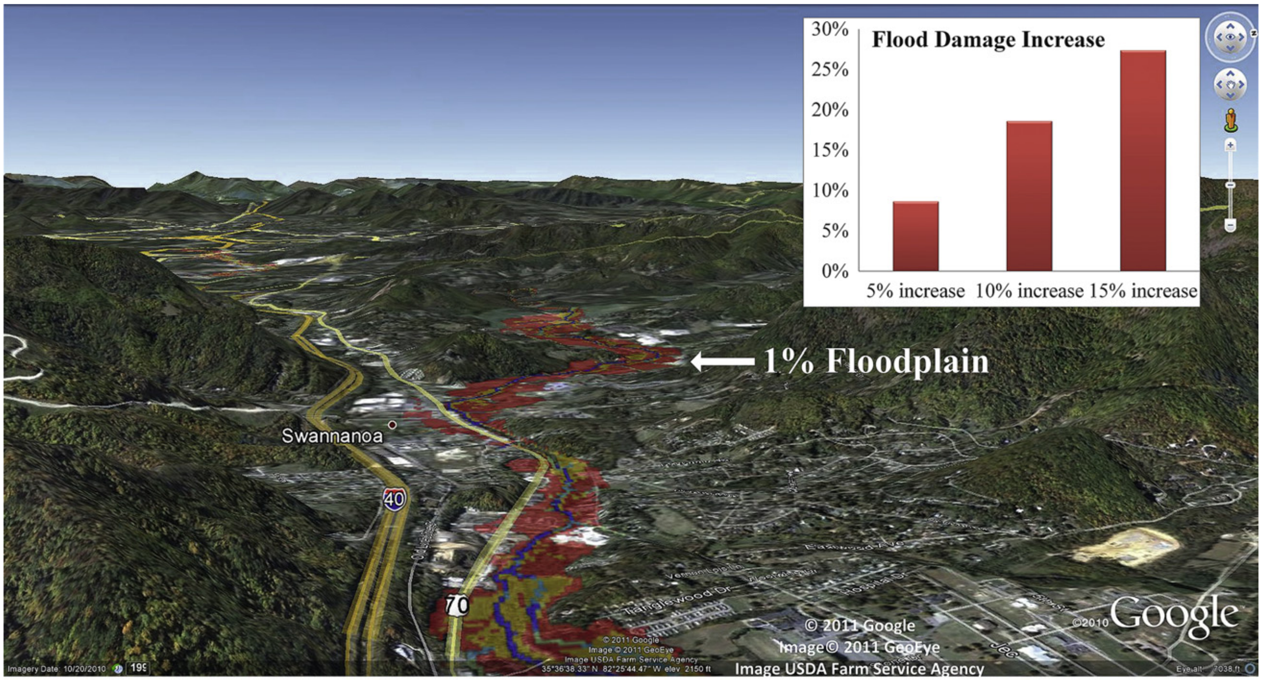

Figure 2 Sensitivity of flood damage increases for reach of the Swannanoa River. The colored area encompassing the river represents the flood inundation extent from the 1% event (i.e., 1% floodplain).

when compared to the climate for which the water systems were built (Willems and Vrac 2011 provides an example for Belgium). A direct vulnerability from these responses is on the increasing economic burden from flooding. For example, an analysis in Swannanoa, North Carolina, indicates the flood damage increases may not be linear with flow rate increases. A 15% increase in flow in the Swannanoa River was discovered to produce a 25% increase in flood damages using a calibrated HEC-RAS model provided by the North Carolina Floodplain Mapping Program (G&O 2007) and flood damage framework of Kalyanapu (2011) (Figure 2). While the majority of the stormwater management and flood control infrastructure is designed without considering a changing climate, it is important to consider how to realistically include the pressures of climate variability and long-term change on stormwater and flood control planning, design, and operation.

Climate vulnerabilities and adaptation strategies are unique to a community, county, state, or region. Vulnerability assessment and adaptation require interdisciplinary participation from stakeholders, politicians, city planners, green area managers, hydrologists, and economists (Arnbjerg-Nielsen and Fleischer 2009). These strategies vary widely based on vulnerability assessments for regions, with different climate and topographic characteristics (e.g., coastal vs. inland, hilly regions vs. plains, arid vs. wet regions), as they are directly related to inherent climate vulnerabilities. Adaptation strategies for stormwater management and flood control may generally include (Montalto et al. 2007; Hallegatte et al. 2010; MOE 2010; Pyke et al. 2011; USACE 2011; WICCI 2011): applying hydrologic and hydraulic models to simulate extreme events; regularly testing drainage system performance; retrofitting existing stormwater storage facilities to capture higher runoff volumes; stormwater harvesting and reuse; implementing source control best management practices (BMPs); identifying possible upgrades to appropriate green infrastructure; educating homeowners about water conservation; strengthening flood control structures to ensure safe passage of higher flood waves; addressing nonstationarity of historical precipitation estimates in hydrologic and hydraulic design of infrastructure; taking an integrated flood-risk management approach; considering both structural and nonstructural flood control alternatives; implementing feasible, cost-effective green infrastructure (see Section 5.06.3.1 of this chapter); improving vulnerability assessments (including bottom–up approaches) at the project level; and developing quantifiable measures to evaluate adaptation effectiveness. Table 2 summarizes some possible adaptation options to stormwater and flood infrastructure corresponding to various climate pressures on water cycle changes. It is important to note that the adaptation strategies may have variable effects on the urban water system vulnerabilities since performance may vary at different spatial scales (e.g., local subcatchment vs. regional river basin scale).

5.06.2.3 Wastewater

Wastewater collection and treatment infrastructure includes septic tanks, sewer pipes, lift stations, treatment facilities, storage tanks, and other appurtenances (US EPA 2012). Wastewater in developed areas is managed using decentralized septic systems or centralized sewers and treatment facilities depending on density, both of which have been identified to possess numerous vulnerabilities to natural and anthropogenic climate variability longer-term change. In the United States, the need to manage sewer flows has been met via conveyance systems, which historically have been categorized as either sanitary sewer systems (SSSs) or combined sewer systems (CSSs) (Marsalek et al. 1993; Burian et al. 1999, 2000; US EPA 2004, 2012). According to the Clean Water Act, CSSs convey domestic, commercial, and industrial wastewater and stormwater runoff through a single pipe system, whereas SSSs convey domestic, commercial, and industrial wastewater, with limited amounts of groundwater and stormwater, through a single pipe system (US EPA 2004). Application and management of these systems has mostly been based on analysis of stable climatic and stationary hydrologic conditions (Kundzewicz et al. 2008; West et al. 2009). Design of CSSs allowed for proper management of dry weather flows, while wet weather flows added strain to the flow-handling capacity of the system, thereby leading to CSO events. As of 2004, there were 746 US communities with an estimated total annual CSO volume exceeding 850 billion gallons of untreated CSS water released to receiving water bodies. Alternatively, while less common, SSSs are estimated to release between 3 and 10 billion gallons of untreated water annually via sanitary sewer overflow (SSO) events (US EPA 2004).

Water-carriage sewage systems are the predominant paradigm used in US cities. They require copious amounts of water to collect and transport human waste to treatment facilities. Water demand for toilet flushing is among the highest percentage of residential per capita water use (e.g., 27% of total indoor water use in Utah, according to Utah DWR 2011). Climate vulnerability to this system is very high if water availability is changed by climate variability or long-term change.

The effect of future climate on the sewer conveyance systems results in a greater prevalence of wet weather events resulting in CSOs, since SSSs are less affected by infiltration and stormwater increases. This leads to enhanced wastewater system vulnerabilities, such as increased hydraulic loadings to wastewater treatment plants (WWTPs) and increased concentrations of pollutants (i.e., well-removable sewage-based contaminants and nutrients during wet weather events) released to the environment (Niemczynowicz 1989; Polaskova et al. 2006; Kundzewicz et al. 2008; Semadeni-Davies et al. 2008; Weyrauch et al. 2010). This leads to reduced treatment performance of WWTPs, adds to both capital and operating costs, and increases the amount of pollutants discharged to the receiving environment.

WWTPs located in coastal areas would be exposed to SLR and therefore would be subject to inundation and damages (Kirshen et al. 2008a). SLR would create significant problems with respect to discharge and backup into gravity-fed sewer lines that outfall to the sea. The consequence is expected to be decreased carrying capacity and a higher potential for CSO events (Burton et al. 2005). This will require substantial infrastructure modifications to provide unimpeded discharge of treated effluent. Similarly, an increase in stream levels from greater amounts or intensities of precipitation events would increase the potential for infrastructure damages and flooding of prone areas. Dependent upon the magnitude of changing groundwater levels, wastewater systems could experience either a gain or a loss of conveyance volumes, leading to increased dilution and infrastructure damages due to the presence of surrounding water or increased concentrations and potential groundwater contamination, respectively (Foster 1990).

Hydrologic responses affect both the quantity and quality of a watershed's water resources and have been found not to be limited to only small receiving bodies, as was the traditional focus of CSO studies (Semadeni-Davies 2004; Weyrauch et al. 2010). More importantly, regardless of any alterations in climate, the increasing growth and concentration of human population within urban centers and smaller cities alone will lead to greater demands and strains applied to the wastewater system (Rosemarin 2005). Thus, it is imperative for local governments to carry out vulnerability assessments that take into account climatic changes and also include other factors affecting an area's water resources (US EPA 2010a).

As described in **Table 2**, adaptation measures seek to increase storage capacity in CSSs to prevent or reduce CSO events and to implement full-cost pricing of water resources via analysis of the economics of the urban water life cycle, while others aim at increasing ecological sanitation measures and highlighting greater efficiency in water use, such as the EcoSanRes Programme (Commonwealth of Australia 1997; Kirshen et al. 2008b; Rosemarin 2005). In flood-risk coastal zones, either flood protection may be required at treatment facilities and their outfall locations or the facilities may need to be moved altogether. Other adaptive measures include recycling and reuse of treated wastewater, movement toward an SSS, use of decentralized alternative sanitation systems (see Section 5.06.3.2), improving treatment capacity to meet increased volume (e.g., provision of increased storage) or contaminant concentrations (e.g., enhanced treatment), and expanding pump system capacity to meet increased hydraulic head caused by storm surges raising the discharge outlet water surface elevation (Kundzewicz et al. 2008; Bates et al. 2008). However, successful adaptation of stormwater management (i.e., integrated urban water management, or IUWM) to climate should decrease the occurrence and magnitude of wastewater vulnerabilities, especially under a CSS (Mitchell 2006).

5.06.3 Toward Sustainable Urban Water Systems

New approaches that seek to achieve sustainability of urban water infrastructure systems have emerged in the past two decades. Approaches are now applying the Triple Bottom Line framework and life cycle analysis to consider solutions that address economic, environmental, and social aspects of projects and take a cradle-to-grave perspective. Addressing climate variability and possible long-term change and other vulnerabilities is important for providing a resilient and sustainable infrastructure system.

One of the important paradigm shifts in managing stormwater sustainably is the concept of low-impact development (LID) introduced in the late 1990s in the United States (Prince George's County 2000). LID concepts encourage introduction of green infrastructure (GI) practices that help achieve the goal of restoring the natural hydrologic cycle. In Section 5.06.3.1, the role of GI in climate vulnerability and adaptability of urban water infrastructure systems is presented. Another new approach to urban water management is decentralization. The action of taking management of urban water away from centralized treatment, distribution, and collection systems has emerged as potentially a more sustainable approach.

Decentralized approaches are briefly highlighted in Section 5.06.3.2. Lastly, in Section 5.06.3.3 we consider the important interconnection of energy requirements with urban water infrastructure systems and how this interconnectedness provides the opportunity to improve sustainability.

5.06.3.1 Green Infrastructure

The US EPA defines LID as a method of land development (or redevelopment) that functions in tandem with nature in order to provide source control, or as close to the source as possible, of stormwater. Principles behind LID include mimicking and preserving natural features of the landscape, minimization of impervious areas that contribute to water quantity and quality issues, and providing an interactive and aesthetically pleasing environment for users. By harmonizing these standards, LID has the ability to possess multiple values, encompassing the three spheres of sustainability: economic, social, and environmental (US EPA 2011c). GI, in the context of LID, is defined as any system or practice that uses or mimics natural processes in order to infiltrate, evapotranspirate, or reuse stormwater or runoff on the site where it is generated (US EPA 2011c). Examples of GI practices include, but are not limited to, bioretention gardens, permeable pavement, grassed swales, green rooftops, and constructed wetlands. GI practices have important influences on the urban water cycle that lead to benefits that improve urban water infrastructure sustainability (Burian and Pomeroy 2010).

Vulnerabilities of GI to climate conditions are explained by focusing on the underlying general stormwater management methods provided, such as vegetative, subsurface storage, and surface storage (**Table 3**). Acting upon these methods, any alterations in climate will ultimately affect the quality and quantity issues of stormwater in urban areas. In addition, depending upon the direction and magnitude of climate variability and long-term change and the configuration of the greater, interconnected system of LID, each GI method may experience a range of vulnerabilities. Refer to **Tables 3 and 4** for examples of potential vulnerabilities.

Since the health of vegetation is subject to climate conditions, practices employing this method are directly sensitive to climate, possibly resulting in reduced plant efficiency and plant disease and death. Indirect vulnerabilities include the introduction of nonnative species or weeds, leading to a reduction of both native species and plant diversity (Hauser et al. 2009). Indirect vulnerabilities also include the health and diversity of macroinvertebrates, such economic requirements as supplemental irrigation during times of drought, and groundwater recharge (Bisgrove and Hadley 2002; Green et al. 2007a; US EPA 2010c).

Table 3 Green infrastructure methods (for use with **Table 4**)

Green infrastructure practice	*Methods employed*
Bioretention	Vegetative, subsurface storage, surface storage
Permeable pavement	Subsurface storage
Grassed swale	Vegetative, subsurface storage, surface storage
Green rooftop	Vegetative, subsurface storage
Constructed wetlands	Vegetative, surface storage

Subsurface storage may be vulnerable to climate variability and long-term change due to its potential for slow recharge rates, groundwater contamination (i.e., contaminants and salinization), and changing water levels (Sugita and Nakane 2007). Once polluted, groundwater may prove difficult to remediate (U.S. EPA 1992). Groundwater recharge may also be affected, either seasonally or as a result of increasing surface temperatures (van Roosmalen et al. 2007; Taniguchi et al. 2007). Other vulnerabilities include a greater potential for inundation of the storage layer, thereby reducing the unit's capacity for stormwater management and, with a higher contaminant load being applied to the unit, the in situ soil characteristics and surrounding groundwater may be affected.

Surface storage may be vulnerable as a result of higher evaporative losses and therefore be associated with salinity issues. In addition, the areal footprint required by surface storage methods may exceed that which is available for proper stormwater management (Keller et al. 2000). Other vulnerabilities include a potential for reduced capacity due to either increased precipitation or elevated groundwater levels, which could lead to a longer duration of erosive discharge flows (determined by the outlet design) to receiving bodies, a higher possibility for vectors, and amplification of contaminant pulses in receiving water bodies (Kaushal et al. 2010).

Similarly, GI adaptations to climate variability can be elucidated by referencing the same generic stormwater management methods provided (**Table 4**). Vegetation provides relief of the urban heat island effect by increasing permeable green space and facilitating ET (US EPA 2008b). Additionally, plants provide water quality treatment and a slowing of runoff via increased roughness, as compared to traditional impervious surfaces such as concrete or asphalt. Subsurface storage offers municipalities with a reliable means of water management, including storage with minor evaporative losses and some water quality benefits. Surface storage provides adaptation to climate change in that it aids in dampening, via distributed collection, urban hydrologic responses, such as flooding and peak flow rates (Keller et al. 2000; US EPA 2011b).

However, more information regarding both the individual scale and greater network of LID practices is required, which should lead to a suite of adaptation strategies that will permit the greatest amount of flexibility when anticipating future climate scenarios, regardless of the direction that climate change occurs (Vorosmarty et al. 2000; Sophocleous 2004; Fletcher et al. 2007; Green et al. 2007b). In doing so, this will lead to different metrics of system performance, exceedances, and consequences (Berggren 2008), thereby bringing to light the adaptation potential of GI, which is high due to flexibility of site scale design and 'retrofitability' within the urban environment. Large-scale stormwater management structures will be more difficult and costly to implement in a retrofit situation. Additionally, just as under historical climate conditions, such stormwater management techniques are dependent upon the local and antecedent conditions and require consistent maintenance, which is a key to the success or failure of both the individual and overall local government management network (Claytor 2003). Sustainability requires active participation by

Table 4 Green infrastructure method responses to climate vulnerabilities and adaptation potential

Method	*Pressure*	*Vulnerabilities to climate*	*Adaptations to climate*
Vegetative	Increased precipitation	May cause inundation; plant disease or death	Slows and intercepts runoff, thereby dampening urban hydrological response; reduction in flood and landslide potentials; dampen the urban heat island effect; decreased in-stream erosive forces and turbidity
	Decreased precipitation	May require supplemental irrigation; plant death	Removal of higher pollutant concentration loads from applied runoff
	Altered precipitation timing	May damage cover (shorter time to peak); may inundate (longer time to peak)	Can dampen result (e.g., flooding) of increased magnitude of urban hydrologic response; decreased in-stream erosive forces and turbidity
	Increased precipitation intensity	May damage cover	Slows and intercepts runoff, thereby dampening urban hydrological response; reduction in flood and landslide potentials; dampen the urban heat island effect; decreased in-stream erosive forces and turbidity
	Decreased precipitation intensity	None	Removal of higher pollutant concentration loads from applied runoff
	Raised groundwater table	May cause inundation of root zone or above; plant disease or death	None
	Lowered groundwater table	May require supplemental irrigation; plant death	Increase storage capacity; increase infiltration ability
	Increased ET	May require supplemental irrigation; plant death	Enhance vegetative ability to use water; enhance ability to infiltrate applied runoff; dampen the urban heat island effect
	Sea level rise	May cause inundation; may cause unwanted salt infiltration; plant death	Defense against saltwater intrusion's effect on vegetation
Subsurface storage	Increased precipitation	May decrease efficiency or capacity; groundwater mounding potential; freeze–thaw potential near surface	Dampen urban hydrologic response (e.g., flooding and increased in-stream flows); decrease in-stream erosive forces and turbidity
	Decreased precipitation	None	Increase storage capacity for precipitation events
	Altered precipitation timing	May inundate unit if flashier event	Depends on local conditions; increase storage capacity if less flashy of an event
	Increased precipitation intensity	May decrease efficiency or capacity; groundwater mounding potential; freeze–thaw potential near surface	Dampen urban hydrologic response (e.g., flooding and increased in-stream flows)
	Decreased precipitation intensity	None	Removal of higher pollutant concentration loads, some water quality benefits
	Raised groundwater table	May reduce capacity and efficiency; groundwater mounding potential; freeze–thaw potential near surface	None
	Lowered groundwater table	None	Provide areas for direct groundwater replenishment
	Increased ET	None	Less evaporative loss, compared with surface storage; dampen urban heat island effect (minor)
	Sea level rise	May cause destruction or inundation	Provide specific zones of porous media, facilitating infiltration of seawater
Surface storage	Increased precipitation	May inundate, causing overflow; increased vector potential (e.g., standing water as breeding ground for mosquitoes)	Intercept runoff; dampen urban hydrologic response; dampen urban heat island effect; decrease in-stream erosive forces and turbidity
	Decreased precipitation	None	Increase storage capacity for future events
	Altered precipitation timing	May inundate, causing overflow or damage if flashier event	May increase storage capacity if less flashy
	Increased precipitation intensity	May inundate, causing overflow	Dampen urban hydrologic response; decrease in-stream erosive forces and turbidity
	Decreased precipitation intensity	May increase contaminant concentration in applied runoff	Collect and provide settling of contaminant load, prior to discharge or infiltration (some treatment)
	Raised groundwater table	May inhibit infiltration capacity, causing reduction in storage and potential for overflow	Provide specified zones of ponding of water
	Lowered groundwater table	None	Increase ability to infiltrate, thereby allowing greater storage capacity; treatment via infiltration and settling
	Increased ET	May increase susceptibility to evaporation, leading to contaminant issues (e.g., salinity)	Dampen urban heat island effect
	Sea level rise	May cause destruction or inundation; may increase contamination (e.g., salinity)	Provide specified zones for management of seawater, if designed specifically with higher salinity loads in mind

both citizenry and government, with education, coordination, and oversight provided by maintenance plans and vulnerability assessments.

5.06.3.2 Decentralization

The design of water, stormwater, and wastewater infrastructure has evolved with established, although not always accurate, understanding of flood control, disease, and public health (Burian et al. 1999, 2000). As an outcome of its historical development, urban water infrastructure designs are predominantly based on a centralized concept and the use of one quality of water for many (and in some cases, all) uses. The centralized approach is giving way under certain circumstances to decentralized approaches to meet water supply, stormwater management, and wastewater management needs (Maher and Lustig 2003). This subsection provides a brief review of decentralization approaches.

In contrast to centralized stormwater management, the decentralizing action of minimizing a directly connected impervious area can reduce runoff volumes, rates, pollutants, and cost for drainage infrastructure by directing the runoff generated by an impervious surface to a pervious area (Guo 2008). This process employs practices such as LID, Water Sensitive Urban Design (WSUD), and GI, which treat stormwater as a resource (Maher and Lustig 2003). In addition, application of distributed, or decentralized, management approaches to reconnect the hydrologic cycle and provide storage or additional treatment (Huber et al. 2006) has the potential to reduce downstream infrastructure capacity needs (Guo 2008).

Such approaches combine "a set of practices that mimic natural processes to retain and use stormwater…[by] promoting infiltration, evapotranspiration, and harvesting throughout the landscape" (US EPA 2010b). Common applications in water-abundant regions such as the northeast and northwest United States, these practices hold potential for greater research and use in arid and semi-arid regions as well, such as in the western and southwestern United States.

The cumulative benefits of widespread, decentralized stormwater management practices have the capacity to accumulate over time, incorporating both large- and small-scale actions, and contribute to the overall resource sustainability of regions. For instance, the preservation and restoration of natural landscape features (such as forests, floodplains, and wetlands in urban environments) provide large-scale protection to ecologically sensitive areas, as well as the application of numerous distributed site-specific practices (US EPA 2011c). In cases where LID is applied, significant savings are realized due to reduced costs for site grading and preparation, stormwater infrastructure, site paving, and landscaping (US EPA 2007). Other benefits include a reduction or delay in stormwater runoff volumes, improved groundwater recharge, a reduction in sewer overflows, increased potential for carbon sequestration, mitigation of the urban heat island effect, a reduction in energy demands, improved air quality, enhanced biota health and habitat, additional recreational space, reduction in stormwater pollutants, improved human health, and increased land values (US EPA 2011c). These are clear opportunities to reduce vulnerabilities, mitigate climate change, and provide for adaptation benefits of urban water infrastructure systems. Life-cycle assessments of GI have shown such approaches reduce greenhouse gas (GHG) emissions, environmental impacts, life-cycle cost, and in general provide a more sustainable option when assessed by the Triple Bottom Line compared to traditional solutions (Spatari et al. 2011).

However, despite the benefits, decentralization of stormwater management could make it harder to ensure that the owners operate and maintain the practices properly (Maher and Lustig 2003). To address this concern, we believe a system of oversight, or checks and balances, could be implemented and adapted by communities, placing stakeholders in charge of construction and maintenance. This would maintain both efficiency and reliability of the units while improving the education and connection of residents to the hydrologic cycle within the greater watershed.

Further research is also needed to quantify the environmental benefits that can be achieved through the use of LID techniques and the costs that can be avoided (US EPA 2007). It is important to reduce these costs, since they can amount to more than $400 billion for capital investment and capitalized costs of $540 billion for operation and maintenance of stormwater control facilities in the United States (Huber et al. 2006). Additionally, more research is needed to monetize the cost reductions that can be achieved through improved environmental performance, reductions in long-term operation and maintenance costs, and reductions in the life cycle costs of replacing or rehabilitating infrastructure (US EPA 2007), which goes part and parcel with the environmental and biological integrity of urban and urban-associated areas.

Although the decentralization practice of rainwater harvesting (RWH) possesses the ability to alleviate the water quantity and quality problems associated with climate variability and longer-term change, the overapplication of such units has the potential of being a detriment to receiving water health (Coombes and Barry 2007; Fletcher et al. 2007). In a study modeling the impacts of RWH across differing levels of urbanization (i.e., imperviousness) for the Australian cities of Brisbane and Melbourne, researchers determined that both quantity and quality indicators [i.e., total runoff, frequency of runoff, total suspended solids (TSS), total phosphorous (TP), and total nitrogen (TN)] could be returned to predeveloped levels; however, where higher rainfall intensities were experienced, this led to less reliability of RWH to alleviate quantity issues. Overextraction of precipitation was simulated for Melbourne under varying combinations of development and demand, and the results posed the scenario of starving receiving bodies of the required environmental flows.

In addition to decentralization of stormwater and water supply, alternative decentralized sanitation approaches are being introduced. Examples include dry sanitation systems such as composting toilets and no mix toilets (Gajurel et al. 2003; Tonner-Klank et al. 2007; Hotta and Funamizu 2009; Rossi et al. 2009). These approaches have limited vulnerability to climate, yet provide a measure to adapt to reduced water supply challenges facing water-carriage sewer systems. Another decentralization measure that provides an adaptation of the sanitation and water supply system is gray-water reuse (Goddard 2006; Memon et al. 2007) and treatment of wastewater onsite (Meuler et al. 2008). Both measures would reduce a vulnerability to limited water supply and provide a reduced demand on the wastewater collection and treatment system.

5.06.3.3 Energy Interdependency

It has become apparent that climate vulnerabilities and adaptation related to urban water infrastructure systems must consider energy requirement. A 2005 study by the California Energy Commission (CEC) found that the energy requirement for water-related services was about 19% of the total electricity demand and approximately 34% of all natural gas demand for the state (CEC 2005). The study received much publicity after its release when water managers realized the implications of such a high-energy demand and began to review their own water supply and energy needs. As a follow-up to the report, Stokes and Horvath (2009) reviewed the energy required to meet California's projected water demand in 2030 using a broad range of potential water sources—from imported surface water to recycled water to desalinated sources. They found that the method chosen to meet California's increasing water demand had a tremendous impact on how much energy might be used as well. Specifically, their study indicated that California's energy use in the future could increase from the current percentage of 19% of its energy budget to up to 52% if planners chose more energy-intensive methods such as desalination. Their study also indicated that surface water imported to the state is one of the least energy-intensive sources of water. However, this method of water provision is also likely the most vulnerable to climate variability and longer-term change. In a scenario that includes declining precipitation and more erratic surface water hydrology, water managers may opt to replace surface water sources with more energy-intensive ones, such as deep groundwater or desalination, which in turn would increase emissions and exacerbate the condition (CEC 2005). This, combined with existing overdraft practices within some water systems, would create a 'lose–lose' situation wherein the resource becomes depleted and the cost to lift more water to the surface rises prohibitively (CEC 2006). The overarching message from the Stokes study was simply that the choices made by water planners and decision makers today could propagate into the future and have unintended and possibly negative effects. It also pointed to some of the other drivers – in this case, a rapidly growing water demand – aside from climate variables that could introduce shortages to urban water systems and result in conflict (Zimmerman et al. 2008).

A study similar to the CEC's report concerning water services was conducted for Utah by Larsen and Burian (2011), which estimated the percentage of Utah's total energy budget used for water services to be approximately 7%. This study highlighted some of the geographic advantages states may have that can facilitate water supply services. For example, the snow pack and reservoir storage of water supplies in the mountains adjacent to the Salt Lake City metropolitan area provide a pressurized supply of high-quality water, requiring very little energy to convey or to treat. However, climate variability and longer-term change may lessen the availability of surface water supply with many attendant drawbacks mentioned above. Water agencies that are already heavily reliant on, or are currently mining, their aquifer resources may adjust to surface supply shortage by accelerating those withdrawals and see their energy costs rise in tandem. Groundwater sources require a great deal of energy to lift water to the surface, and the amount of energy required increases as the water table drops. Secondary impacts derived from the necessity of increased pumping, treatment, and pressurization include the cost of additional power generation infrastructure, the cost of new dams or storage infrastructure to capture more runoff, and the attendant GHG emissions that accompany more energy-intensive processes and facilities. Depending on the energy mix of the region (coal is the primary component of Utah's energy portfolio), added contributions of GHGs and other harmful pollutants could be substantial. And finally, as pumping is also one of the primary costs to water utilities, substantial increases in groundwater withdrawals could have an immediate impact on the financial standing of some districts.

The implications of declining surface water supply in terms of energy requirement were investigated and quantified for a case study water system in Utah (Larsen and Burian 2011). The Jordan Valley Water Conservancy District (JVWCD) is a large wholesale and retail water system situated in the southwestern quadrant of the Salt Lake Valley. Smaller member-agencies are comprised of local governments and other water district customers, which in turn supply and sell water directly to retail customers. In total, JVWCD and its member agencies serve more than half of the population living in the Salt Lake Valley. Their water supply sources include snowmelt runoff – imported via tunnels, diversions, and canals over 480 km – from the high Uinta Mountains to the Salt Lake Valley. They also supplement this supply with an array of groundwater wells, especially over the summer months when demand for outdoor irrigation water is higher. Retail agencies purchase water from JVWCD but may also supplement these purchases with groundwater wells within their district boundaries or from other sources. Using an energy estimation tool for water services created by Larsen (2010), an estimate of JVWCD energy requirement for water services under a climate change scenario was evaluated. The model assumed that groundwater supplies were adequate and a reduction in available surface water supply would be compensated for with an increase in groundwater withdrawals. Groundwater withdrawal estimates were made based on historic surface water availability for the district during and after a prolonged drought, groundwater withdrawals, and other climate variables (a reasonable assumption for the JVWCD and other water providers in the American West). Figure 3 is a graph of the estimated increase in energy requirement from additional compensatory groundwater pumping for JVWCD. The figure shows an estimated increase in energy for a low- and a high-energy-use range with incremental reductions in available surface water. A 20% reduction in surface water is estimated to result in 3.3 million kWh per year increase in energy consumption due to additional groundwater pumping, while a 35% reduction amounts to approximately 5.8 million additional kWh per year for the low-range system.

JVWCD is one of the larger urban water agencies that are situated to take advantage of snow pack runoff and gravity-fed network pressurization in Utah. Other agencies either purchase from water wholesalers or rely more heavily on groundwater. For example, Salt Lake City Public Utilities' water supply sources vary from year to year, but it relies significantly on

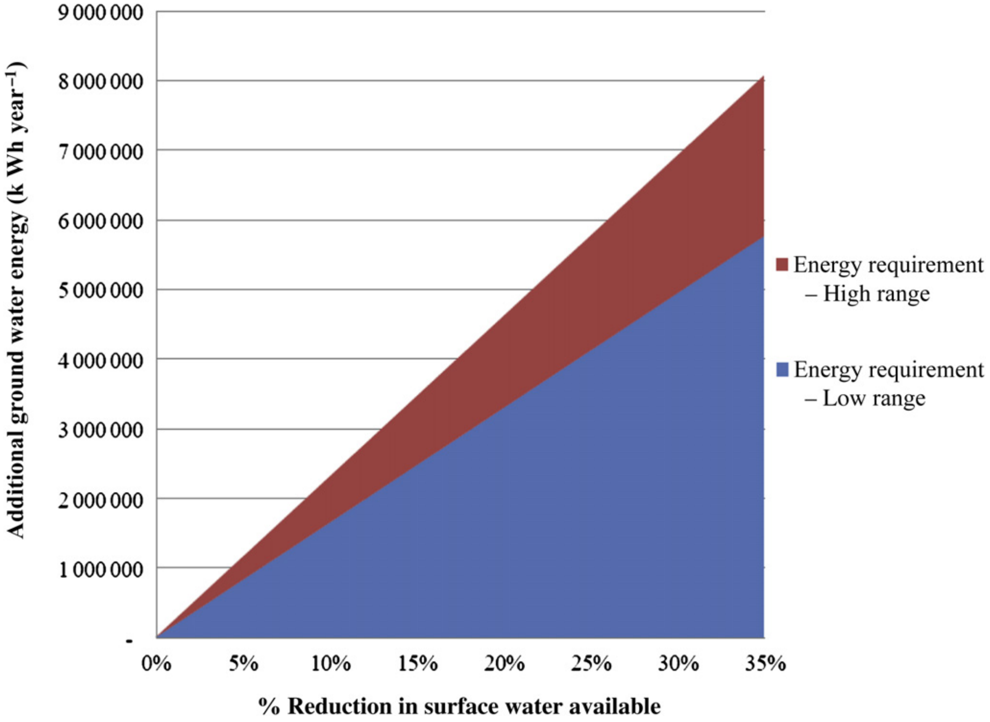

Figure 3 Additional energy requirement for JVWCD, the wholesale district, with decreasing surface water availability.

water withdrawals made from deeper aquifers in the Salt Lake Valley, which requires additional pumping to provide pressure to the system. Because of this, their energy requirement for water withdrawals and pressurization is significantly higher than a simpler surface water source and gravity-fed network. Savings for more energy-intensive water systems are also greater than a gravity-fed system if the agency is able to assist its customers in adopting a water conservation ethic. For example, using a case study site in Melbourne, Australia, Flower et al. (2007) found that, with a combination of structural and nonstructural demand management strategies, individual household water consumption could be reduced by 65% and indirect GHG emissions could be reduced by 63%. An interesting corollary is that the CEC also suggested that it may be possible to meet 95% of their energy efficiency goals indirectly through less-expensive water efficiency programs, emphasizing the gains to be made in the end-use sector for that region (CEC 2005; Alliance for Water Efficiency 2008).

Both initial water treatment and wastewater treatment are also large energy users within the water supply and consumption cycle and the energy requirement varies with the water quality of influent and the technology employed at the facility. Increased turbidity in incoming flow is likely to require additional treatment processes and infrastructure. More advanced water treatment methods such as ozonation, ultraviolet light disinfection, or additional nutrient removal are more energy intensive as well (EPRI 2002). Removal of higher concentrations of endocrine disrupting compounds requires very energy-intensive processes such as reverse osmosis treatment (Benotti et al. 2009). On the wastewater end, changes in the hydrologic cycle may also disrupt processes by concentrating effluent before it arrives at the plant, flooding facilities that discharge in coastal waters, or increasing water temperatures to a degree that they damage sewer and stormwater infrastructure or the biological processes that effectively remove contaminants. Reduced in-stream flows may also concentrate pollutants at a facility's outfall, eventually resulting in increasing water quality treatment standards within the plant to maintain the health of the public and ecosystems downstream. More stringent water quality regulation requires more extensive (and energy-intensive) infrastructure and processes.

Mitigation specific to the energy requirements of urban water systems under climate variability and change scenarios requires adaptive planning from the macroscopic view down to the individual water component. State agencies and district managers that are most familiar with the region or local area should incorporate energy costs (both actual and financial) and their resulting 'carbon footprint' into their extended-horizon cost/benefit analyses concerning resource development and capital improvements. Entities concerned with planning and administration of both water and energy may coordinate their efforts to make decisions that optimize the use of both resources. Water planning decisions that include and attempt to minimize energy expenditure improve the resiliency of the water system and provide an additional buffer against fluctuating energy pricing. Incorporating renewable energy sources (such as on-site solar, wind, or geothermal power) into urban water systems also improves resiliency when there are fluctuations in energy supply, allowing for critical water provision or treatment during natural hazards or events that interfere with power infrastructure. Diversifying water supply portfolios to include less traditional water sources like recycled water also minimizes energy costs where redistribution is not extensive. Colocation of water treatment and energy production facilities has been found to conserve a significant amount of energy by utilizing the same infrastructure components (intakes and outfalls) and by passing water used in the cooling processes of the power facility directly on site for treatment. Including biogas or cogeneration capacity at wastewater treatment plants also provides a substantial amount of energy that can increase resiliency at the plant and even serve as a potential energy offset (Show and Lee 2008). Finally, water education and conservation programs, including incentives for water- and energy-saving household appliances and fixtures, can be one of the most effective mitigation and adaptation tools available to water policy-makers.

Incorporating energy requirement on a water agency or district scale could include a multitude of the same strategies presented above but on a smaller scale. Such entities can foster adoption of a long-term water conservation ethic by participating in water education programs; offering incentives for water-conserving appliances, fixtures, and xeric landscapes; and implementing a staggered pricing structure for water use that encourages conservation and makes exorbitant water use more expensive. Other more infrastructure-centric strategies may also serve as a means to improve urban water system efficiency. Components of a water distribution or treatment system can often increase their energy efficiency by optimizing pump and groundwater operation (Bunn and Reynolds 2009) or by using a Supervisory Control and Data Acquisition (SCADA) system, as suggested by EPRI (1998, 1999), or characterization of water networks into hydraulic modeling software (Ramos and Ramos 2009). Likewise, implementation of a maintenance, inspection, and asset management program can point out problem areas of the system where additional energy savings may be realized and allow for interyear comparisons of component performance and operation. Finally, the incorporation of new technologies as they become available may also prove beneficial. An example might include investigating the potential for energy cost offsets with the selective removal of pressure reduction valves in favor of small hydropower energy generation or microturbines (Ramos and Mello 2007; Smith 2008). Whatever the method employed, meeting water demand in the future will require decision makers and agency managers to make smart choices that incorporate and address energy requirements and consider the two resources in tandem.

Most of an urban water system's vulnerability to climate variability concerning water and energy nexus topics can be described as a function of how much energy is necessary to maintain water services and how much energy will be needed in the future given climate and population growth drivers. How much water is necessary for energy and electricity generation is of less importance to the manager or director of a water district or agency than whether there is adequate energy to run the facilities. However, current trends in energy use, and projections to meet that use in the future, have ramifications for urban water systems. Several researchers have noted that the municipal per capita water use in the United States has leveled off in recent decades (Diamond and Moezzi 2004). The water withdrawals necessary for energy production have not, and are projected to increase in tandem with energy needs (Sovacool and Sovacool 2009). Water planners may need to take this new demand sector into account when looking for water supply sources to meet future demands. An example would be a city that is expecting transfers from agricultural uses to municipal systems to supply an expanded population. If a new generation plant is built nearby that is water intensive, the agricultural water may or may not be available to the city when the time comes to transfer. Climate variability, especially the prospect of reduced streamflows, would increase the competition between urban water systems and other sectors for any available supply.

5.06.4 Conclusion

This chapter reviewed climate vulnerabilities and adaptation approaches of urban water infrastructure systems. Taking an integrated approach, water supply, stormwater, and wastewater systems were considered together. Although the response of systems to climate variability is highly site and system specific, the chapter highlighted general vulnerabilities and adaptation strategies. A broader vulnerability concept requires the determination of the major threats to these resources from climate considerations and from other social and environmental issues. After these threats are identified for each resource, then the relative risk from natural and human-caused climate change can be compared with other environmental and social risks in order to adopt the optimal mitigation/adaptation strategy. Future climate has the real possibility resulting in increased energy use (Elcock 2010), coastal flooding and SLR (Purvis et al. 2008), river flooding, transportation problems, water supply problems (Gleick and Chalecki 1999), a decrease in public health, decreased water quality, increased bridge scour, and many other challenges to urban water infrastructure. An important part of the assessment of the challenges and developing solutions is to identify synergistic effects among the often independently operated subsystems of water supply, stormwater, and wastewater. Moreover, solutions to adaptation should be broader than presented in this chapter to be a part of a coherent regional strategy to ensure sustainable water resources.

An important limit to the analysis presented in this chapter is the narrow scope of the system considered. The system boundary considered is the urban water infrastructure system, which is linked to many other subsystems in cities as well as systems that are connected to urban areas, including agriculture, regional energy generation, regional water, and so on (Kirshen et al. 2008b), many of which are highlighted in this volume. Future systems analysis work will need to continue to expand to include the detailed considerations presented here along with those of the broader connectivities.

One other limitation is the focus on climate vulnerabilities. Urban water infrastructure systems are exposed to an array of pressures leading to vulnerabilities, including population growth, land use change, policy, and aging infrastructure. Future work must consider the relative importance of climate variability compared to the other pressures on the systems, which of course changes case by case. It is also expected that climate vulnerabilities of urban water infrastructure systems will be heightened when combined with pressures from urbanization, social change, and so on. This is especially likely for systems that are already stressed by existing conditions.

Typically, changes to urban water management that address vulnerabilities in general and climate vulnerabilities in particular approach urban water management in an integrated manner. The systemic nature of an urban watershed, especially when the drainage system works jointly with flooded urban landscape elements, makes it possible that some design solutions act in an ineffective way; however, it is also possible to attain better results via strategies applied in coordination with one another. Broadening this thought is the concept of IRP that takes a long-term portfolio approach where diversifying and integrating flexibility into the system leads to resilience. A key part of IRP is stakeholder involvement. The use of these broad approaches also requires the use of multicriteria decision-making approaches to evaluate urban watershed management alternatives based on achieving multiple objectives (Chung et al. 2011).

Besides new urban watershed management approaches, there are emerging technologies, policies, and interconnected factors that will serve to help systems adapt to climate variability and longer-term change and other vulnerabilities. Challenges with new approaches are typically related to policy, designer/planner experience, and cost. Local government design criteria for buildings and other infrastructure are, in general, not changing in response to the observed variability and longer-term changes in climate. Flood control and drainage design, for example, are based on frequency analysis of historical rainfall and streamflow data, which may not reflect recent or future climate. The recent economic downturn has helped to inhibit changes to policy that would require greater expenditures to provide the increased levels of protection; therefore, solutions from policy and funding perspectives are, in some cases, more important than technical guidance. For instance, Philadelphia's (Pennsylvania) Green City, Clean Waters is a 25-year plan that aims to protect and improve the watershed's stormwater problems resulting from its CSS, via LID application (Philadelphia Water Department 2011). In 2007, the State of Maryland passed the Stormwater Management Act, requiring all new developments to implement environmental site design to the maximum extent practicable, which highlights sustainable and better site design techniques (Boicourt et al. 2011). In San Jose, California, the Green Vision is a 15-year plan that provides the city with a road map to attain sustainability, via balancing of economic, environmental, and social community aspects (City of San Jose 2010). Other cities, such as Chicago, provide the population with several examples and additional resources available online to improve water resources sustainability (City of Chicago 2010).

Several strategies aiding the move toward more sustainable and resilient urban water infrastructure systems were noted. Implementing GI to manage stormwater provides a low-cost, ecologically focused approach to provide capacity to reduce stormwater runoff quantity and improve quality addressing challenges introduced by climate vulnerabilities. Decentralization of the water supply through rainwater harvesting provides redundancy but is also vulnerable to climate variability. Decentralized sanitation approaches and gray-water reuse present excellent opportunities to reduce the demand for potable water by helping to address the climate vulnerability of existing centralized water supply infrastructure systems. Last, the importance of considering the water–energy nexus was highlighted as an opportunity for reduction of resource consumption and harvesting of energy potential. The emerging approaches to urban watershed management display vulnerabilities to climate variability and change pressures; however, the improved resiliency they provide when applied in conjunction with centralized elements may be superior to centralized systems alone. More research is needed in general and on case-by-case basis.

5.07.1 Introduction

On January 19, 2011, an unusual weather event occurred. The National Weather Service Web site (http://www.crh.noaa.gov/news/display_cmsstory.php?wfo=ddc&storyid=62980&source=0) described the event in the following way: "the atmosphere was cold and moist with low clouds and fog preceding the formation of the snow. It appears that two slaughter plants and a power generating plant (upwind of the region) contributed to the snow as ice nuclei and copious amounts of water vapor were fed into the boundary layer. East/southeast winds carried the vapor and nuclei aloft into the lower clouds and then precipitated out as snow downwind (**Figure 1**) of the source. Snowfall of as much as 0.7″ was reported in the snowfield with no snow observed at all outside of this area." The snowfall plume is apparent in Doppler radar images (**Figure 2(a)**) and satellite depictions of snow cover (**Figure 2(b)**).

Though unusual, this example illustrates how human activity in an urban environment affected a precipitation event. The scholarly literature continues to indicate that urbanization, deforestation, irrigated landscapes, impounded structures, and pollution can alter the frequency, intensity, or occurrence of precipitation (Mahmood et al. 2010). In fact, the Intergovernmental Panel on Climate Change (IPCC) (Trenberth et al. 2007) specifically mentioned an emerging interest in how urban environments—the focus of this discussion—modify hydrometeorological and climate system. While the climate discourse has been primarily centered around greenhouse gas emissions, urban climate effects are conclusively documented.

Seto and Shepherd (2009) stated that "the built environment characterized by urbanization is a significant forcing function on the weather-climate system because it is a heat source, a poor storage system for water, an impediment to atmospheric motion, and a source of aerosols (e.g., pollutants)." **Table 1** (adapted from Seto and Shepherd 2009) presents multiple ways that urbanization can impact hydrometeorological and climate processes.

The most common manifestation of urban climate is the urban heat island (UHI). The UHI is typically characterized by warmer skin, surface, and canopy temperatures in urban landscapes due to heat-retaining materials (e.g., asphalt, concrete), lack of vegetation, and excessive anthropogenic heat sources. Surface geometry (e.g., as expressed by sky view factor) is also an important element of the UHI; surface geometry also increases the surface area for solar absorption, leads to multiple reflections and decreased albedo, and affects turbulent transport (sheltering effects). All of which impact the UHI. Grimmond et al. (2010) and Yow (2007) are excellent resources for information on the energetics, thermal properties, and dynamics associated with UHIs.

UHIs are somewhat common in both scientific and public vernacular. It is a conclusive example of human alteration to the Earth's climate system. However, the literature has also revealed that urban landscapes and associated pollution may also alter components of the water cycle, particularly clouds, precipitation, and land surface hydrology (Bentley et al. 2010; Niyogi et al. 2011; Grimmond et al. 2010; Hidalgo et al. 2008; Mills 2007; Shepherd et al. 2010a, 2011). The motivation herein is to review the theoretical and physical basis for how urbanization influences the spatiotemporal nature of precipitation and convective activity. This is particularly important for the following reasons:

1. For the first time in history, the majority of the world's population lives in urban environments (Hand and Shepherd 2009) and this number will increase to over 80%

by 2030 (UNFPA 2007) (Figure 3). This means that urban land cover and air quality degradation will continue to expand and expose more people to vulnerabilities associated with urban climates.

2. Convective processes and precipitation are critical components in the global water cycle and a key proxy for climate, but they exhibit variability at a range of scales from local to global.
3. Urban–hydrometeorological–atmospheric interactions have major societal implications for weather forecasting, climate diagnostics and prediction, flood management, water resource management, urban planning design, and agriculture.

5.07.2 Vulnerabilities in the Coupled Human Natural System

It is clear that the urban rainfall effect (URE) is of scientific interest because there are clear linkages to contemporary research and forecast problems in meteorology, climatology, hydrology, and geography systems. However, precipitation in an urban setting is strongly coupled to key societal processes and decision trees. An array of vulnerabilities may be linked to urban precipitation climatologies and variability:

1. Urban flooding: Jurisdictions are increasingly interested in the complex interplay of the urban environment and the atmospheric and land surface components of the water cycle. Shepherd et al. (2011) raised important questions about whether storm water management, drainage systems (Burian et al. 2004), and urban planning consider the shifting precipitation regimes associated with large-scale climate and urban climate. For example, hydroclimate experts have warned that current urban flood assessment and storm water management are based on hydroclimate stationarity assumptions and outdated assumptions concerning rainfall intensity and frequency. Intensity, duration, and frequency resources and methodologies must be modified to reflect nonstationarity and new understanding of local-to-regional hydrometeorological forcing.

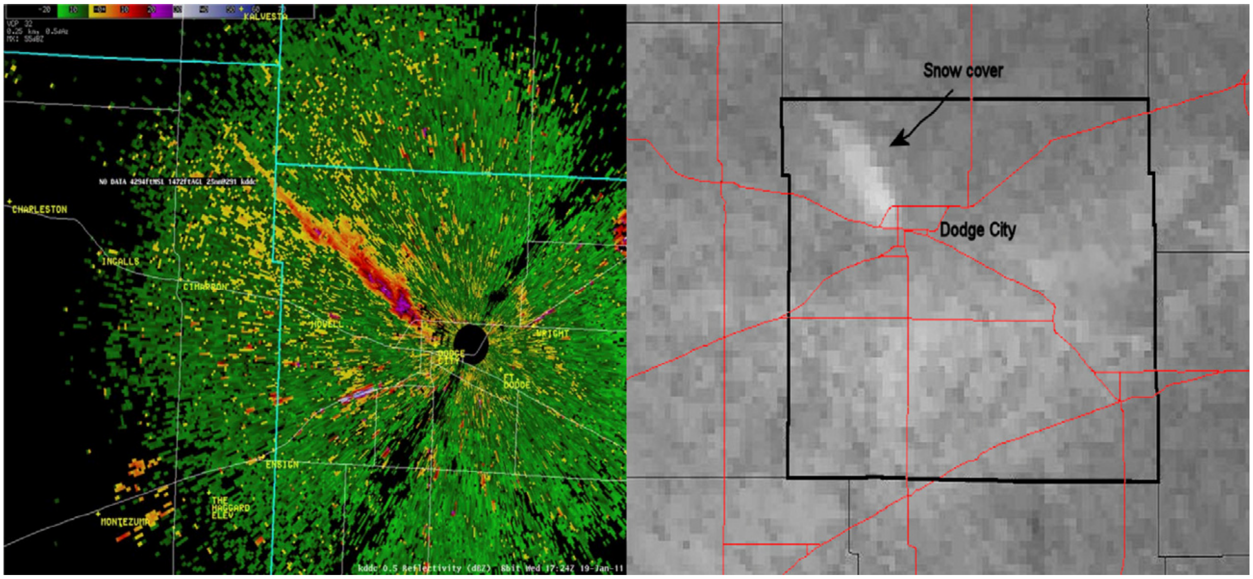

Figure 2 Dodge city snow event as captured by a (a) radar image at 1124 LST and (b) satellite image after the event. Source: National Weather Service; Shepherd J. M. and T. L. Mote, 2011: Can cities create their own snowfall?: what observations are required to find out? Earthzine, Special Urban Monitoring Theme Issue. Available online at http://www.earthzine.org/themes-page/urban-monitoring/.

Table 1 Alterations of surface and atmospheric processes by changes in urban land cover, urban aerosol loading in the atmosphere, and anthropogenic greenhouse gas emissions

Weather or climate processes	*Urban land cover*	*Urban aerosols*	*Anthropogenic greenhouse gas emissions*
UHI and mean surface temperature record	Surface energy budget	Insolation, direct aerosol effect	Radiative warming and feedback
Wind flow and turbulence	Surface energy budget, urban morphological parameters, mechanical turbulence, bifurcated flow	Direct and indirect aerosol effects and related dynamic/thermodynamic response, dispersion, and transport	Radiative warming and feedback
Clouds and precipitation	Surface energy budget, UHI destabilization, UHI meso-circulations, UHI-induced convergence zones	Aerosol indirect effects on cloud–precipitation microphysics, insolation effects	Radiative warming and feedback
Land surface hydrology	Surface runoff, reduced infiltration, less evapotranspiration	Aerosol indirect effects on cloud–microphysical and precipitation processes	Radiative warming and feedback
Carbon cycle	Replacement of high net primary productivity land with impervious surface	Black carbon aerosols	Radiative warming and feedback, fluxes of carbon dioxide
Nitrogen cycle	Combustion, fertilization, sewage release, runoff	Acid rain, nitrates	Radiative warming and feedback, NO_x emissions

Adapted from Seto, K., and J. M. Shepherd, 2009: Global urban land-use trends and climate impacts. *Curr. Opin. Environ. Sustain.*, doi:10.1016/j.cosust.2009.07.012.

2. Urban planning: It is reasonable to consider how contemporary and future cities are planned. Stone et al. (2010) and Shepherd et al. (2010b) have shown that urban land cover is a significant driver of climate at the urban and associated regional scales. Such research is intriguing and raises questions about urban governance and the inclusion of urban hydroclimate science in policy and decision making. It is not unreasonable to consider the planning of an urban landscape with an eye toward mitigating or maximizing precipitation for a region's agriculture or water supply needs.
3. Public health: Urban precipitation climatology may be associated with an array of health issues, ranging from West Nile virus to asthma. Socioeconomics and public health practices are first-order factors, but it is plausible that areas which may experience more rainfall in an urban regime could be more susceptible to water-borne diseases (e.g., dysentery or cholera) or vector-borne diseases (e.g., malaria, dengue, and West Nile virus). Further, thunderstorms were associated with more hospital admissions for respiratory distress and asthma for metropolitan Atlanta, Georgia (Grundstein et al. 2008).
4. Water resource management: In the face of increasing drought and the need for additional surface water supply, Shepherd and Mote (2009) have argued that future water supply reservoirs might be placed in urban rainfall anomaly regions to optimize recharge, particularly in the warm season. For example, Mote et al. (2007) noted that eastern

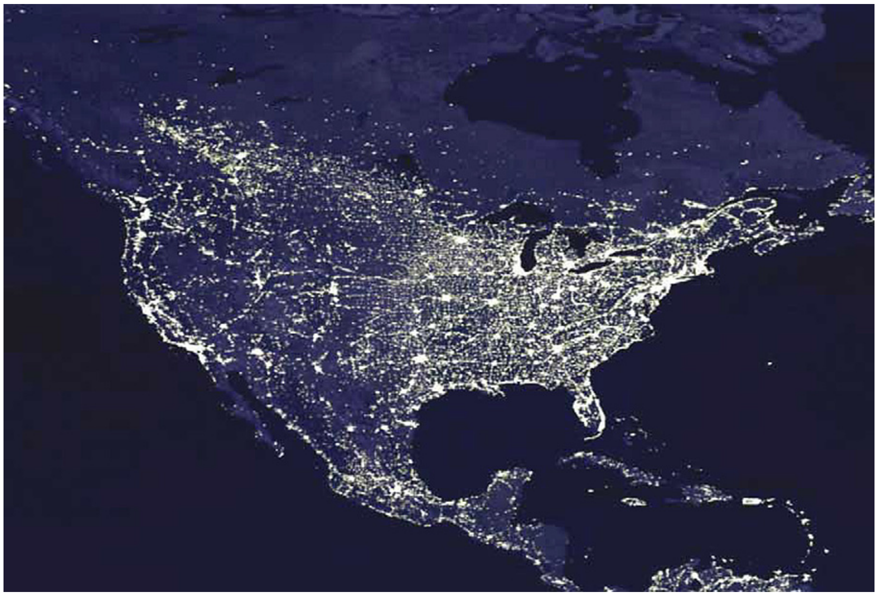

Figure 3 Defense Meteorological Satellite Program (DMSP)/Optical Line Scanner (OLS) data showing lights at night in the United States. Source: NASA (http://www.nasa.gov/vision/earth/lookingatearth/NIGHTLIGHTS.html). The lights, to a first order, are a proxy for urbanization.

suburbs of Atlanta (within 50–100 km) receive more warm season rainfall (more on this in later sections), yet Figure 4 shows that this region has no new reservoirs planned.

5. Strategic systems management: The placement of new agricultural lands, sensitive electrical infrastructure, flood management, or industrial facilities might be informed by knowledge of urban lightning or precipitation anomalies.

Mote, 2009: Urban effects on rainfall variability: potential implications for Georgia's water supply. Proceedings of the 2009 Georgia Water Resources Conference, 6 pp.*

Clearly, urban weather and climate are integrated in the economics of urban regions. Such costs might include flood damages, airport closures, health-insurance costs, or regional transportation infrastructure. Snowstorms in 2010 and 2011 crippled Washington, DC (i.e., 'Snowmaggedon') and revealed cascading scales of vulnerability ranging from the poorest citizen of the District of Columbia to the President of the United States.

A rare tornado in the central business district of Atlanta, Georgia, in 2008 and the crippling tornado outbreak in Joplin, Missouri, in 2011 reveal potential infrastructure vulnerabilities and the need to consider severe weather in urban building codes. Thomas (2011) recently discussed the vulnerabilities of hospitals to severe weather in light of the Joplin event. She notes that "… extreme weather can cause building failures that ultimately lead to interruptions in the continuity of care. The impacts are not momentary. From post traumatic stress disorder to the costs of structural rebuilding, the affects can be long-lasting. Yet, structural mitigation, while not a full panacea, can offer some protection to keep buildings and people safe. The World Health Organization (WHO) calculates that the price for retrofitting the non-structural items (e.g., moveable carts, trays) costs as little as 1% of the value of a hospital, while possibly protecting up to 90% of the hospital's assets. According to FEMA, the most common points of hospital failure from storms are the elevator crankcases, windows and generators. Bolstering protection of these building assets costs magnitudes less than the cost to rebuild." While specific to hospital infrastructure, such recommendations are relevant to any urban building infrastructure facing the threat of increased storm activity or flooding.

While urban changes to the hydroclimate have been discussed herein, one must not overlook the coupled influenced and heightened vulnerability due to the background climate gases (Seto and Shepherd 2009). Reports, composed of international expertise, continue to call for renewed resources and research to address urban hydroclimate interactions (Dabberdt et al. 2000; NOAA OFCM 2004; NRC 2012).

5.07.2.1 Controversy Over the Sign of Change

Though methods and data availability continue to improve, there is still uncertainty and scientific debate about whether urban environments increase rainfall, decrease rainfall, or have no effect on rainfall. The consensus in the literature suggests that some type of enhancement is the dominant sign change; however, other results are compelling (see Section 5.07.2). However, it is worth noting that there is some literature that finds conflicting results, albeit a relative minority of studies. Hughes (2006) found no statistical evidence supporting UREs in cities of the United Kingdom, although she did not rule them out either. Matheson and Ashie (2008) found in modeling simulations for Tokyo that rainfall was increased or decreased due to the inclusion of the city, as a function of the prevailing wind. However, their results do suggest that urban landscape can modify precipitating systems. Trusilova et al. (2008) coupled atmosphere–land surface (CALS) model simulations of European climate sensitivity to urban land cover offered mixed results. Shepherd et al. (2010a) summarized their results by noting that they found "statistically significant increases (decreases) in winter (summer) precipitation in their urban simulations as compared to the pre-urban simulations." This study was interesting but used fairly coarse model resolution (10 km) and cumulus (not explicit microphysics) parameterization for cloud–precipitation processes.

Kaufmann et al. (2007), using statistical and econometric models, found evidence of reduced precipitation after urban development throughout the Pearl River Delta of China. They suggested that reductions in surface hydrology could explain the changes. Guo et al. (2006) used a similar argument to explain decreased cumulative rainfall around Beijing. Zhang et al. (2009) showed that urban land cover in Beijing reduced ground evaporation and evapotranspiration, which was important for rainfall formation. One important factor that was missing in the studies describing precipitation suppression in Asia is aerosols or pollution.

Aerosols (e.g., pollutants) have been shown to suppress precipitation. This inverse relationship between aerosol load and precipitation has been summarized in Lin et al. (2011), Stjern et al. (2011), and Rosenfeld et al. (2008). Asia is a heavily polluted region and a thorough climatological assessment of precipitation change in the region must consider the recent trends in the spatiotemporal aerosol distribution. Recent studies (Rosenfeld et al. 2008; van den Heever and Cotton 2007) have explored the role of giant cloud condensation nuclei (CCN) (enhancement) and smaller CCN (suppression). However, the synergistic role of urban aerosols and land cover on precipitation is still not conclusive and requires additional study. It is likely that topography, meteorology, aerosol type, and continentality determine the order of influence of aerosols. For example, Jin and Shepherd (2008) argued that aerosol effects are more dominant on maritime cloud droplet formation. Stjern et al. (2011) found no statistical evidence that aerosols have affected drizzle or light rain climatologies in Europe. Lin et al. (2011) firmly established the inverse relationship between aerosols and precipitation.

5.07.3 Historical Evidence of the 'URE'

While contemporary methods and studies have advance knowledge of the URE, it is useful to consider the historical legacy of this field. Horton (1921) observed that thunderstorms seemed to develop over large cities. Kratzer (1937, 1956) further advanced the notion of urban alteration of precipitation. However, the pioneering text 'The Climate of Towns' by Helmut Landsberg (1956) elevated the possibility that large urban areas affect rainfall. Over the next several decades, more research emerged on the topic. Several studies were focused on a hypothesis that industrial, urban regions southeast of Chicago, Illinois, such as La Porte, Indiana, had enhanced cumulative precipitation due to urban or aerosol effects. Stout (1962) and Changnon (1968) led early investigations related to the 'La Porte Anomaly' although they were inconclusive (Lowry 1998). More importantly, these early studies stimulated the first golden age in research on the topic.

The prevailing hypothesis in early studies, many advanced by European scholars, was that rainfall was enhanced primarily over or downwind of urban areas (Landsberg, 1970; Huff and Changnon, 1972a,b). A major North American field program, the METROpolitan Meteorological EXperiment (METROMEX), was a large-scale effort to test such hypotheses and advance scientific understanding of urban precipitation climatologies and physical mechanisms. A key legacy of METROMEX is that it provided some of the earliest and most rigorous hypotheses about physical forcing of urban hydroclimate interactions. METROMEX employed many observational strategies including special rain gauge networks, balloon soundings, and weather radar. Shepherd et al. (2010a) summarized key findings from the series of scholarly publications from this multicity investigation:

1. Enhanced cumulative precipitation (see **Figure 5** as an example) by urban effects are typically 25–75 km downwind of a city during warm season months (Changnon et al. 1977; Huff and Vogel 1978; Changnon 1979; Braham 1981),
2. Cumulative amounts were enhanced between 5 and 25% over background values (Changnon et al. 1981, 1991), and
3. The size of an urban area influenced the horizontal extent and magnitude of urban enhanced precipitation (Changnon 1992).

Lowry (1998) raised questions about the methodologies and research framework applied during METROMEX and post-METROMEX studies. He further hinted that such deficiencies could 'create' the anomaly regions. His recommendations, summarized below, would provide key guidance to contemporary studies on urban rainfall. Lowry (1998) recommended:

1. "Designed experiments—especially legitimate controls and, where appropriate, stratification schemes—in which explicitly stated hypotheses are tested by means of standard statistical methods.
2. Replication of the experiments in several urban areas.
3. Use of spatially small, and temporally short, experimental units reflecting the discontinuous nature of precipitating systems.
4. Disaggregation of standard climatic data to increase sample size and avoid merging effects between dissimilar synoptic weather systems."

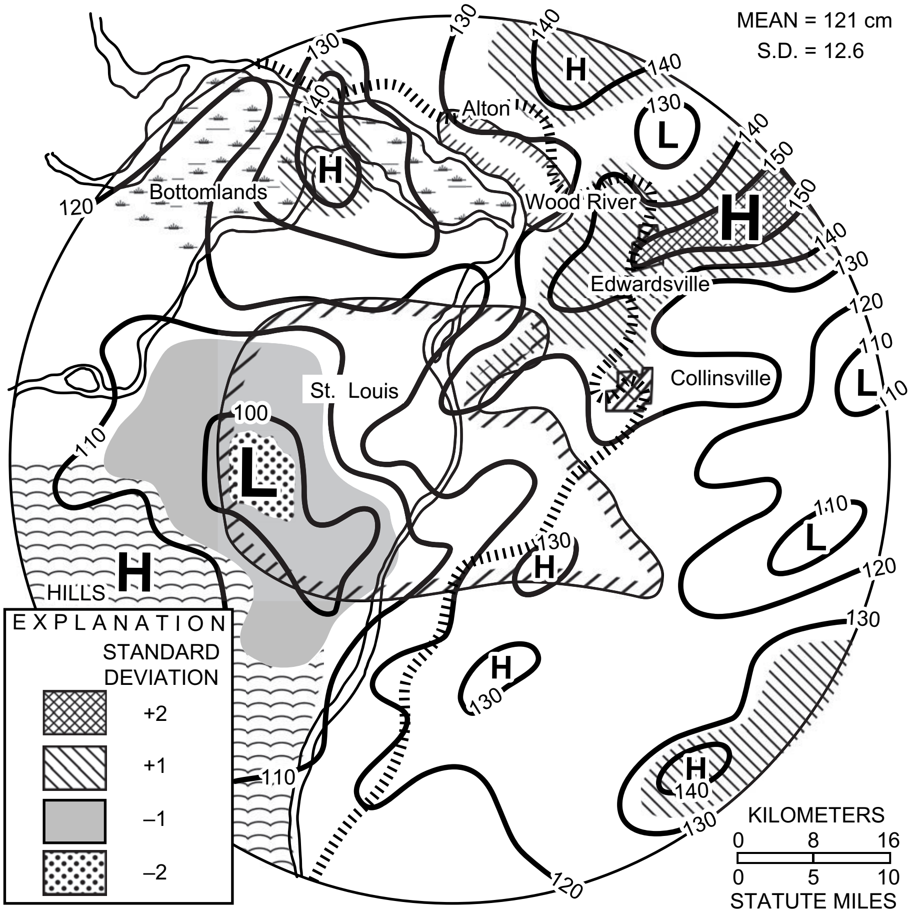

Figure 5 METROMEX, total summer rainfall (cm), 1971–75. Source: Changnon, S. A., F. A. Huff, P. T. Schickedanz, and J. L. Vogel. 1977. Weather anomalies and impacts: In summary of METROMEX Vol. I. Illinois State Water Survey Bulletin 62, 260 pp.

As noted earlier, the literature has found conflicting results to METROMEX Tayanc and Toros (1997) found no evidence that four large Turkish cities had modified climatological rainfall patterns. Robaa (2003) argued that an inverse relationship may exist between urbanization and cumulative precipitation around Cairo, Egypt. In future sections, other recent findings that support or refute the METROMEX results are discussed. The text will also explore the physical mechanisms that link urbanization to precipitation changes. Aerosols – for example, their concentration, size, and to a lesser extent composition – have been shown to suppress or enhance precipitation and/or lightning (Rosenfeld et al. 2008). Regardless of the sign of the change, it is clear from the literature that urbanization alters the hydroclimate system in diverse ways.

5.07.4 Post-METROMEX Era Perspective

After METROMEX and the subsequent questions about the validity of its findings, momentum on the topic slowed. Balling and Brazel (1987) noted a greater frequency of occurrence of late afternoon thunderstorms around the Phoenix area. They attributed the increase in frequency to rapid urbanization in this otherwise arid region. Selover (1997) noted that moving summer convective storms were altered by Phoenix. Later work by Diem and Brown (2003) and Shepherd (2006) corroborated the notion of a URE in the Phoenix area, particularly in the Lower Verde region of Phoenix. Shepherd (2006) hypothesized that urban-induced mesocirculations might interact with outflow boundaries from the mountain-forced convection to explain the location of the Lower Verde anomaly.

Jauregui and Romales (1996) found significant correlations between the daytime UHI and the intensity of rain showers during the wet season (May–October) in Mexico City, Mexico. They also argued that the frequency of intense rain showers had increased as a result of urban growth. Changnon and Westcott (2002) found a similar tendency toward more heavy rainstorms in recent decades for a selection of urban locations.

Bornstein and LeRoy (1990) were one of the first research groups to study the URE in a 'megalopolis' city. Using weather radar, they found that maximum convective rainfall was found on the lateral edges and downwind of New York City. This study was important because it further demonstrated the value of weather radar to overcome limitations associated with the sporadic nature and point source availability of rain gauges. Precipitation, unlike temperature, is highly variable in space and time, which can be problematic for point source measurements. This study also solidified the notion that cities not only initiate or enhance convection but also modify the structure and progression of storms. Recently, Niyogi et al. (2011), using Doppler radar data, found that the city of Indianapolis, Indiana, modifies a significant number of storms approaching the urban environment. Such studies indicate that the urban effect is not only apparent in the initiation of convection in weak large-scale forcing environments as previously argued, but it can also modify preexisting convection. Shem and Shepherd (2009) found similar results in their modeling simulations of moving convective systems in Atlanta, Georgia.

Shepherd et al. (2002) introduced a new approach for examining the URE. They used satellite-based instrumentation designed to measure precipitation from space. Space-borne estimates enabled the investigation of multiple cities simultaneously as opposed to one or two urban locations. This approach overcomes one of the limitations of earlier work identified by Lowry (1998). On the other hand, the satellite-derived rainfall estimates had relative coarse spatial resolution and well-known measurement biases. Shepherd et al. (2002), using a short 3-year period, found evidence of precipitation anomalies in the climatological downwind region of several major cities in the southeastern United States. Diem et al. (2004) and Shepherd (2004) had a scholarly discourse on the merits of the findings, appropriate scale, and methodologies in Shepherd et al. (2002). Souch and Grimmond (2006) noted that this paper may have 'reinvigorated' the urban climate community on the question of UREs.

Shortly after Shepherd et al. (2002) had published, Dixon and Mote (2003) presented evidence that in the moist environment of Atlanta, Georgia, some nocturnal convective storms might have been initiated by the urban landscape itself. During the same period of time, a Japanese paper, Fujibe (2003), stated that increased convective activity downwind of large cities like Tokyo may be due to the enhanced surface convergence in the urban environment (more in the following sections). Shepherd and Burian (2003) extended the satellite-based methodology to a large coastal–urban complex, Houston, Texas, and found that rainfall anomalies in the data were spatially consistent with lightning flash density anomalies described by Orville et al. (2001). Orville et al. (2001), and later Steiger and Orville (2003), attributed the lightning anomalies to urban landscape or industrial–urban aerosols. Further details are provided in the following sections.

In 2005, Shepherd reviewed the current literature related to urban convection and rainfall effects. While the review was a timely contribution to the literature, he also provided a set of recommendations to move understanding and predictive capability forward on the topic: The recommendations of Shepherd (2005) were as follows:

1. "New observing systems must be developed to monitor and track anthropogenic and natural aerosols, land cover/land use changes, cloud microphysics, and precipitation processes,
2. Modeling systems that explicitly resolve aerosols, cloud microphysics, complex land surfaces, and precipitation evolution so that a more conclusive understanding of the feedback and interactions can be attained,
3. Implementation of urban parameterizations at the local scale to resolve urban canyon, dynamics, and flux processes, particularly in terms of roughness, surface cover properties, low-level moisture associated with irrigation, and aerosols,
4. Field studies to validate satellite observations and modeling simulations of urban-precipitation processes and to extend basic understanding of the processes involved,
5. Climate modeling systems that adequately characterize the urban environment are required to understand the aggregate roles of global urban surfaces on the Earth's climate system, particularly the precipitation component of the water cycle under different growth and climate scenarios,
6. Assessment of the impact of urban-induced rainfall on societal applications."

Burian and Shepherd (2005) confirmed the satellite-based results of Shepherd and Burian (2003) by using historical gauge data to show that "urban area and the downwind regions of Houston, Texas (USA) had 59 and 30% respectively greater cumulative rainfall between noon to midnight in the warm season compared to the upwind region." As noted earlier, two studies (Diem and Brown 2003; Shepherd 2006) identified spatial anomalies around the northeastern suburbs and exurbs of Phoenix during the monsoon season. Shepherd (2006) results suggested that the anomaly regions had 12–14% more cumulative precipitation in the posturban (1950–2003) period as compared to the preurban (1895–1949) period. Shepherd argued that outflow boundaries from mountain thunderstorms might be interacting with the urban circulation to explain the location of the anomaly. Simultaneously, Chen et al. (2007) posed a similar hypothesis to explain a nocturnal anomaly around Taipei (Taiwan).

One of the most compelling studies to date is Mote et al. (2007). They employed a radar analysis to look at warm season (2002–06) composites of precipitation climatology. Figure 5 (left panel) shows the greater rainfall totals expected in the Blue Ridge mountains of north Georgia and in the coastal plain to the south. More interestingly, there is an anomaly of higher rainfall amounts over and east of the Atlanta, Georgia, metropolitan area even though, climatologically, the entire area is similar. They found that this 'downwind area' receives up to 30% more warm season rainfall during the evening and early morning hours. It should be noted that this study stratified cased days to remove large-scale forcing, a key recommendation of Lowry (1998). This study is also compelling because it successfully establishes that the radar climatology strongly reveals the mesoscale and topographic signatures of rainfall in Georgia. Diem (2008) extended the epochal analysis of Diem and Mote (2005) to confirm, using long-term climatological analysis, that a rainfall anomaly exists in the northeast suburbs of Atlanta. Bentley et al. (2010) has extended the Mote et al. (2007) radar study and found that an array of downwind 'anomaly' regions may exist and, perhaps, some upwind anomalies as well. This is an important point to mention that, for a given day, upwind and downwind are a function of the prevailing wind such that a downwind anomaly for a given day may differ from the climatological downwind region, which is based on average flow conditions. In a compelling study, Ashley et al. (2012) conducted a climatological synthesis of urbanization effects on an array of cities in the southeastern US using a 10-year radar data analysis. They confirmed "positive urban amplification of thunderstorm frequency and intensity for major cities."

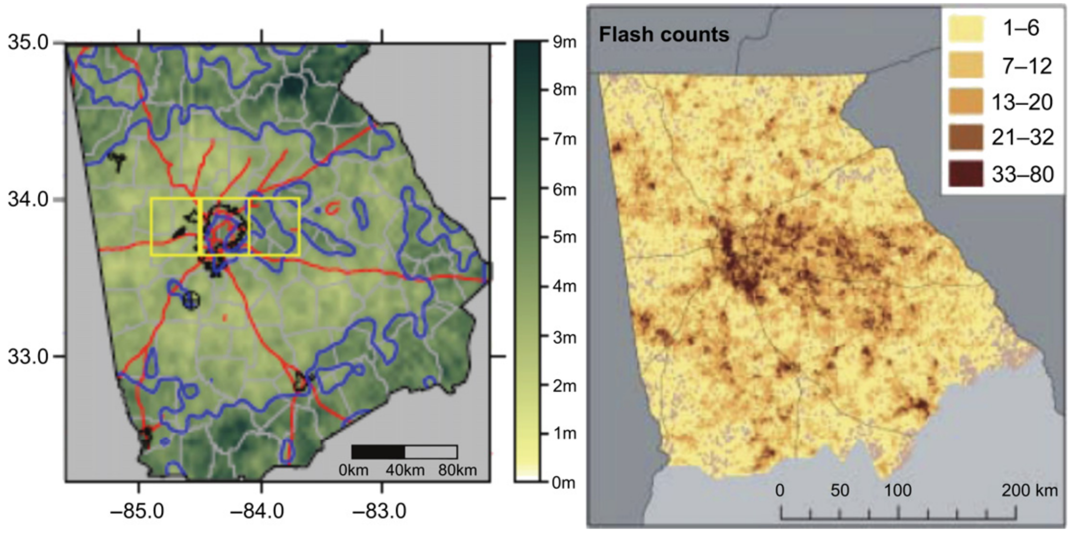

Figure 6 Average daily rainfall (shaded and units of millimeters) from Jun.–Aug. 2002 composited for days with weak atmospheric forcing. The 5-mm contour is shown in blue, and the yellow boxes represent the mean upwind (left), city (center), and downwind (right) regions (Left) and lightning flash anomalies (May–Sep. (1995–2003) on days dominated by weak atmospheric forcing) (right) in Atlanta, Georgia. See Mote et al. (2007) or Stallins and Rose (2008) for further information on methods and data.

5.07.5 Beyond Spatiotemporal Rainfall Climatology: Urban Effects and Other Related Hazards

5.07.5.1 Rainfall Intensity and Frequency

Since the URE is primarily associated with convection, it is logical that urban effects might be observable in other convective-related processes (e.g., heavy rainfall rates, lightning, and flooding). Rose et al. (2008) used cloud-to-ground (CG) lightning data and North American Regional Reanalysis (NARR) rainfall data set to reveal lightning enhancements in the same downwind anomaly region (Figure 6, right panel) identified by Mote et al. (2007). Stallins and Rose (2008) provided an excellent review of urban effects on lightning and highlight several global studies on the topic. The possible mechanism will be discussed later in the text.

Hand and Shepherd (2009) used a blended product called the Tropical Rainfall Measuring Mission (TRMM) Multisatellite Precipitation Analysis and the Oklahoma mesoscale observational network to confirm not only a statistically significant rainfall anomaly in the north–northeast suburbs of Oklahoma City but also a tendency for heavier rainfall events to occur in the same region. This study was novel because it was the first application of a merged satellite product incorporating infrared, passive microwave, and rain gauge data rather than only satellite precipitation radar data. Consistent with Rose et al. (2008), Hand and Shepherd (2009) noted a fairly strong relation between prevailing wind and downwind anomaly regions. More importantly, Hand and Shepherd (2009) also established that such satellite-based estimates are relatively accurate when validated against ground-based rain gauge networks (at the appropriate scale) and can be useful in investigating rapidly developing urban regions around the globe. Basara et al. (2009) discussed a new fine-scale Oklahoma City micronet with observations in the central business district. Such measurements are rare and will enhance our research capacity going forward.

Kishtawal et al. (2009) used historical gauge networks and the TRMM precipitation radar to show that heavy rainfall events increased in urbanized regions of India compared to rural stations (Figure 7). Mitra et al. (2011) also used gauge data and satellite rainfall estimates to study the oft-neglected pre-monsoonal rainfall climatology of India. They found that urban stations in the region of Kolkata, India, have positive trends in pre-monsoonal rainfall. A forthcoming modeling effort by Mitra and Shepherd (personal communication) further confirms that 'Nor'westor' convective systems may interact with the urban landscape to affect the evolution of rainfall in the region.

Halfon et al. (2009) noted increased cumulative precipitation amounts downwind of Tel Aviv, Israel. Chang et al. (2009) noted the role that urban land cover played, through boundary later and flux alterations, on a heavy rainfall event in Mumbai, India. Meng et al. (2007) also used ground radar-based analysis in an innovative study which presented evidence that the urban land cover associated with Guangzhou City (China) intensified thunderstorms associated with a tropical cyclone. Radar echoes were maximized over the urban area as also noted by Shem and Shepherd (2009) and Niyogi et al. (2011). Inamura et al. (2011) used ensemble simulations with a large number of members to investigate the effects of Tokyo's landscape on heavy rainfall. They found that the urban effects of Tokyo modified the wind convergence and rainfall leeward of the urban area. Li et al. (2011) associated rapid urbanization in the Pearl River Delta region of China with an increase in strong precipitation and convective events. Miao et al. (2011) used a mesoscale model with high fidelity representation of urban canopy. Their results confirmed that Beijing can modify storms by splitting them or enhancing the amount of rainfall. They attributed the modification to thermal (sensible and latent heat) transport rather than momentum transport (more on mechanisms later). Zhang et al. (2010) noted in the Yangtze River Delta Economic Belt that urban areas experience 15%

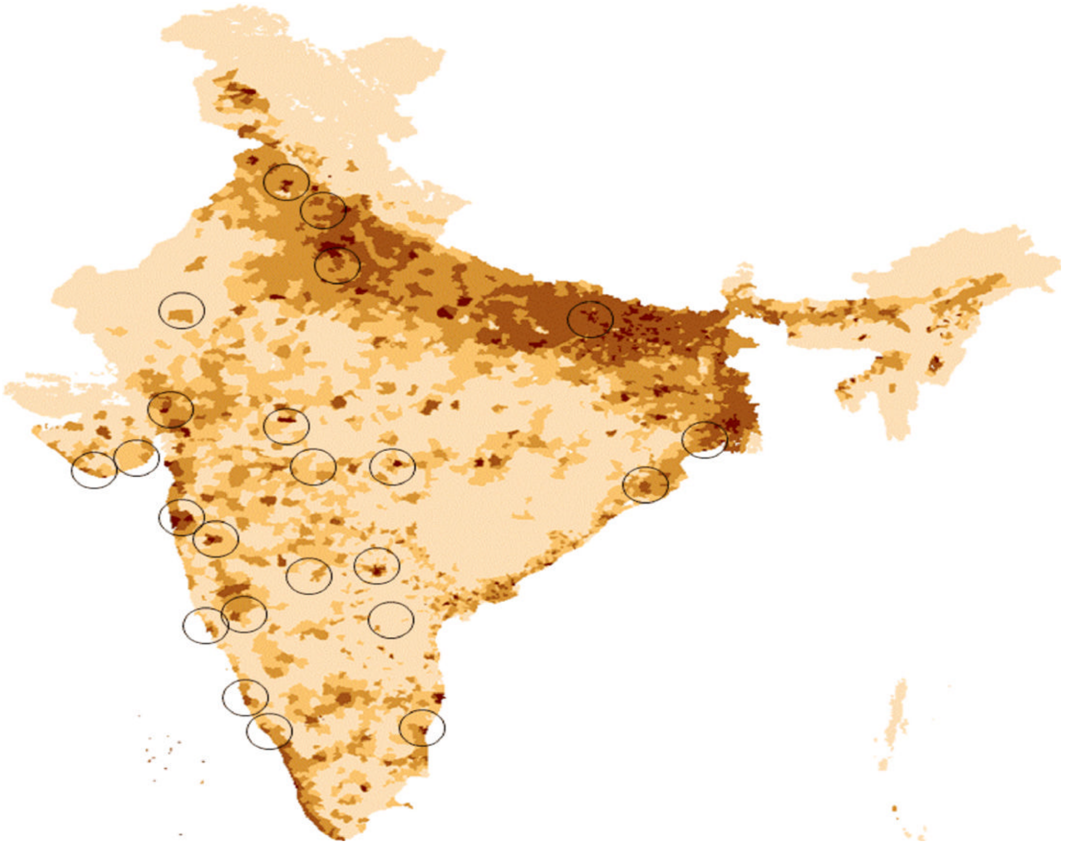

Figure 7 Circles represent the location of stations where the frequency of heavy precipitation events exhibits a positive trend with 99% confidence. The change in population density between 1990 and 2000 is shown in the background (from Kishtawal et al. 2009). Darker colors represent larger changes in population density. The darkest colors are indicators of cities.

more rainfall over the city and leeward, but that the effect was most prevalent during the summer.

5.07.5.2 Flooding

In 2010 and 2011, a number of cities worldwide experienced severe urban flooding. Ntelekos et al. (2007) showed that both the urban landscape and pollution may have assisted in priming the atmosphere for convection that led to flooding in the Baltimore—Washington area. Shepherd et al. (2011) argued that the urban landscape may have enhanced precipitation associated with a large-scale flooding event in Atlanta, Georgia. Though synoptic and mesoscale processes described the 'big picture' flooding event, localized regions of enhancements in the downwind part of the city may have been urban forced (Figure 8). They also confirmed that the urban landscape accelerated the land surface hydrological response. Shepherd et al. (2011) stated that "previous studies have noted the role that the urban environment has on the hydrologic cycle, including runoff, infiltration, evapotranspiration, and precipitation (see Reynolds et al. 2008, for a review). Reynolds et al. (2008) found that impervious surfaces in Houston distributed stormwater to conveyance systems with more volume over a shorter amount of time, which increases the risk of overwhelming the capacity of the system." It is suggested that in considering urban effects on the urban hydrological cycle, one must consider precipitation–urban interactions as carefully as they consider the evapotranspiration–urban or runoff–urban relationships, which tend to be more understood.

5.07.5.3 Lightning

Heavy convective activity and rainfall events are typically associated with lightning. Thus, it is not surprising that researchers have also identified a potential 'urban lightning effect,' The advent of ground-based and space-based lightning detection systems has advanced our ability to investigate this facet of the problem. Two overarching findings have emerged (Stallins and Rose 2008). They are summarized in Shepherd et al. (2010a): "(1) cloud-to-ground negative polarity flash densities increase, particularly downwind of the city center and (2) the percentage of positive polarity cloud-to-ground flashes decrease in the vicinity of cities." The reader should consult Stallins and Rose (2008) for a summary of the range of geographic and climatological regimes that have experienced an urban CG lightning effect.

Studies have mainly noted higher negative CG flash densities and decreased positive flash production within 100 km of the urban center (Stallins and Rose 2008). Because lightning is inherently associated with convection, it is not surprising that lightning and rainfall anomalies around cities would be consistent. This is clearly evident in Figure 5, for example,

around Atlanta, Georgia. More research and more robust hypotheses are required to explain how urban attributes contribute to the noninductive charge separation process (Yair 2008). In this process, graupel–ice crystal collisions in the presence of supercooled liquid water and vertical air currents allow for the accumulation and transfer of negative and positive charges throughout the cloud. Logical questions might center around how urban aerosols might delay the onset of precipitation and lead to a more invigorated, glaciated cloud, as Rosenfeld et al. (2008) argued, and how convective forcing associated with the roughness, UHI, and destabilized urban atmosphere increase the likelihood of convective activity. However, the role of aerosols is strongly supported by a few studies. Stallins et al. (2006) found smaller percentages of positive flashes downwind of long sections of major transportation arteries in Atlanta, Georgia. They argued that the aerosol effect may be detectable ~100 km downwind of the Atlanta central business district. Steiger and Orville (2003) observed higher flash densities and lower percentages of flashes in a Lake Charles–Baton Rouge Louisiana corridor. Of interest, this region has significant aerosol-producing refineries and chemical production facilities but not necessarily a centralized urban landscape footprint. For locales devoid of significant land cover, the spatial association among aerosols, increased flash densities, and decreases in the percentage of positive flashes support a mechanistic role for atmospheric particulate matter.

5.07.5.4 Winter Precipitation

Though very limited and not contemporary, early research on urban effects on snowfall suggested that modified freezing rainfall and snowfall occur over and downwind major US cities because of the UHI (Landsberg, 1981; Changnon, 2003). Molders and Olson (2004) have suggested that snowfall anomalies in Fairbanks may be due to urban effects. Other studies of snowfall enhancement downwind of urban areas have been limited and generally focused on aerosol effects (e.g., Van den Berg 2008; Wood and Harrison 2009). Very little work on urban landscape shape and snowfall response exists because the vast majority of research in the physical geography and urban climate literature has posited that urban affects are most apparent during the warm season when smaller scale convective forcing is dominant (Shepherd et al. 2010a; Bentley et al. 2010; Mote et al. 2007). However, Shepherd and Mote (2011) recently argued that enough preliminary evidence is found in the literature to warrant new research on this topic. Clearly, the example quoted in the Section 1 establishes that humans can modify snowfall.

5.07.6 What Causes the URE?

Even with the uncertainties about the 'sign' of the change in precipitation due to urbanization, it is widely accepted that urban environments 'affect' rainfall processes. Shepherd et al. (2010a) stated that "though several plausible hypotheses for urban effects on rainfall have emerged within the literature, there is no conclusive theory on what mechanisms, independently or synergistically, affect urban rainfall processes. A large body of literature has been devoted to pattern description and visualization. These methods are vital for generating and testing these hypotheses, but emphasis has now shifted to documenting

mechanisms and elucidating relative contributions (Teller and Levin, 2008)." While some questions remain about the 'URE', the topic has received considerable attention recently.

While mechanistic studies have been precise for single case studies, a larger hydroclimatological perspective covering many years and processes is still needed (Shepherd et al. 2010a). However, it is still useful to highlight the leading hypothesis even though one cannot make generalizations about when they are most applicable.

5.07.6.1 Low-Level Dynamical and Flux Processes

Pielke et al. (2007) is a clear reminder that land cover can influence atmospheric processes. These processes are manifested at the surface, boundary layer (Oke 1987), and beyond. However as Lowry (1998) noted, controlled experiments are required. One of the most appropriate 'laboratories' for assessing mechanisms is the physically based CALS model. CALS enables a plausible way to remove or alter land surface, aerosol, topographic, or meteorological features to evaluate atmospheric responses under different scenarios. Figure 9 summarizes how the CALS model interacts to characterize thermodynamic, dynamic, and moisture exchanges.

Post-METROMEX era model experiments provided early evidence that the URE was linked to urban-induced convergence, thermodynamic changes, and surface fluxes. Table 2 summarizes some of the key findings from the period 1979 to 2011.

A common weakness of the studies in Table 2 is the lack of representation of aerosols or pollution. This is somewhat a function of the state of the modeling technology, but next-generation modeling systems are starting to address this deficiency. van den Heever and Cotton (2007) considered urban landscape and aerosol effects in their modeling study of St. Louis. More of these types of studies are required to determine the relative roles of aerosols in the URE.

5.07.6.2 Aerosol Roles

Aerosols are defined in Shepherd et al. (2010a) as "particles in the atmosphere, ranging from 0.01 μm to 10 μm. Urban regions usually have the highest concentration of aerosols, up-to 108–109 particles per cc (Seinfeld and Pandis, 1998). Aerosols can be divided by size: fine mode and coarse mode particles. Coarse particles are composed of mechanical materials such as tire dust, sea salt and natural dust in urban areas. Fine particles tend to be produced locally by construction, air conditioning, transportation, and industry or by chemical interactions [in the atmosphere] involving sulfates, nitrates, ammonium and organics."

Urban aerosols can vary in composition: black carbon, particulate matter, sulfates, nitrates, and others. The direct radiative effect of aerosols scatters or reflects solar radiation. Jin et al. (2011) recently presented evidence that aerosol direct effects can significantly reduce the magnitude of the urban skin temperature heat island, which may in turn affect precipitation processes. Some aerosols, mainly black carbon, may absorb and warm the atmosphere, which may have a large-scale stabilization effect on the atmosphere, thus suppressing cloud

Table 2 Key model studies over the period 1978 to 2011

Authors	*Key finding*
Vukovich and Dunn (1978)	Urban–rural gradients and boundary layer stability primarily describe UHI mesocirculations, which are conceptually similar to sea-breeze circulations
Huff and Vogel (1978)	Sensible heat fluxes and surface roughness associated with urban surfaces transport heat to the atmosphere
Hjelmfelt (1982)	Rising motion linked to St. Louis-induced low-level convergence/translation of the urban circulation by larger-scale advection. Bornstein and Lin (2000) later corroborated this finding by using a special observation network in Atlanta
Thielen et al. (2000)	Weak UHIs are associated with sensible heat flux, buoyancy, and convergence variations at a distance from heat source
Rozoff et al. (2003)	Nonlinear interactions associated with momentum drag, urban surface friction, and heating could induce downwind converge
Niyogi et al. (2006)	Applied urban canopy models embedded in the land surface model. Such models represent 3D urban morphology and heterogeneity rather than simple slab representations of urban surface. Their simulations demonstrated how the urban morphology affects temperature and wind flow
Gero and Pitman (2006)	Dynamical forcing (increased instability and convergent forcing) triggered a convective storm over urban land cover associated with Sydney, Australia
Ikebuchi et al. (2008)	Confirmed that urban land cover and anthropogenic heating altered the location and intensity of convective rainfall around Tokyo
Baik et al. (2007) and Han and Baik (2008)	Used numerical and analytical models to show that boundary layer destabilization leads to a region of intensified rising motion induced by the UHI. These studies also offered a plausible explanation for why urban convective effects can be apparent in the daytime even though UHI magnitude is greater in nocturnal hours (Arnfield, 2003). They reasoned that during daytime hours, stability conditions favor stronger UHI circulations. Han and Baik (2008) also found, using a 3D framework, an internal gravity wave field with a rising branch downwind of the theoretical heat source (e.g., the city)
Shem and Shepherd (2009)	Combined urban-induced convergence associated with urban circulation on the perimeter of Atlanta's urban land cover and increased sensible heat flux contributed to enhancement of convection in Atlanta case studies
Shepherd et al. (2010b)	Enhanced sensible heat flux and low-level convergence associated with urban land cover interacts with sea-breeze circulation near Houston to create regions favorable for convective development. Carter et al. (2012), Lo et al. (2007), Yoshikado (1994), and Ohashi and Kida (2002) have found similar results for Houston, Hong Kong, and Japanese cities. Shepherd et al. (2010b) also used 2025 urban land cover projections to determine future precipitation changes as a function only of land cover change (no greenhouse gases)
Niyogi et al. (2011)	Indianapolis' urban land cover modifies convective system structure, pathway, and intensity

development (Kaufman et al. 2005). However, this aspect of the urban rainfall problem warrants further study.

The indirect effect of aerosols (i.e., aerosols serve as CCN) on precipitation has received most attention in the literature. Twomey (1977) posited that under the condition of finite water vapor availability, more CCN will lead to more competition for water vapor in the cloud–droplet formation process. This process leads to smaller cloud droplets that are not able to grow efficiently or rapidly to produce raindrops. Jin and Shepherd (2008) employed satellite-derived cloud, aerosol, and precipitation properties to confirm the Twomey effect over regions of China and adjacent maritime regions.

The literature is rich with recent discussions on how aerosols affect precipitation (Rosenfeld and Lensky 1998; Rosenfeld 2000; Givati and Rosenfeld 2004; Kaufman et al. 2005; Jin et al. 2005; Lensky and Drori 2007; Rosenfeld et al. 2008; Jin and Shepherd 2008; Stjern et al. 2011; Lin et al. 2011). The prevailing understanding is that larger maritime aerosols enhance the collision–coalescence process, promote larger droplets, and create earlier rainout. On the other hand, smaller aerosols over land counter the collision–coalescence process. This may delay rainout and invigorate the cloud to deeper convection (Rosenfeld et al. 2008). This scenario suggests that suppressed precipitation by urban aerosols (Lin et al. 2011) might be associated with increased electrification and rainfall intensification. Figure 10 presents a summary of such processes and illustrates how suppressed rainfall might lead to an invigorated convective cloud and more electrification. It should be noted, however, that many of the aerosol studies have not focused on urban aerosols and more work is required because there is still a great degree of uncertainty (Stjern et al. 2011).

5.07.6.3 Bifurcation and Other Dynamic Effects

As noted earlier, the presence of buildings, the thermodynamic UHI dome, or a combination of the two can modify local and regional circulations around cities. Both observational and modeling studies continue to confirm that convective cells can be redirected, bifurcated, or altered by the urban landscapes.

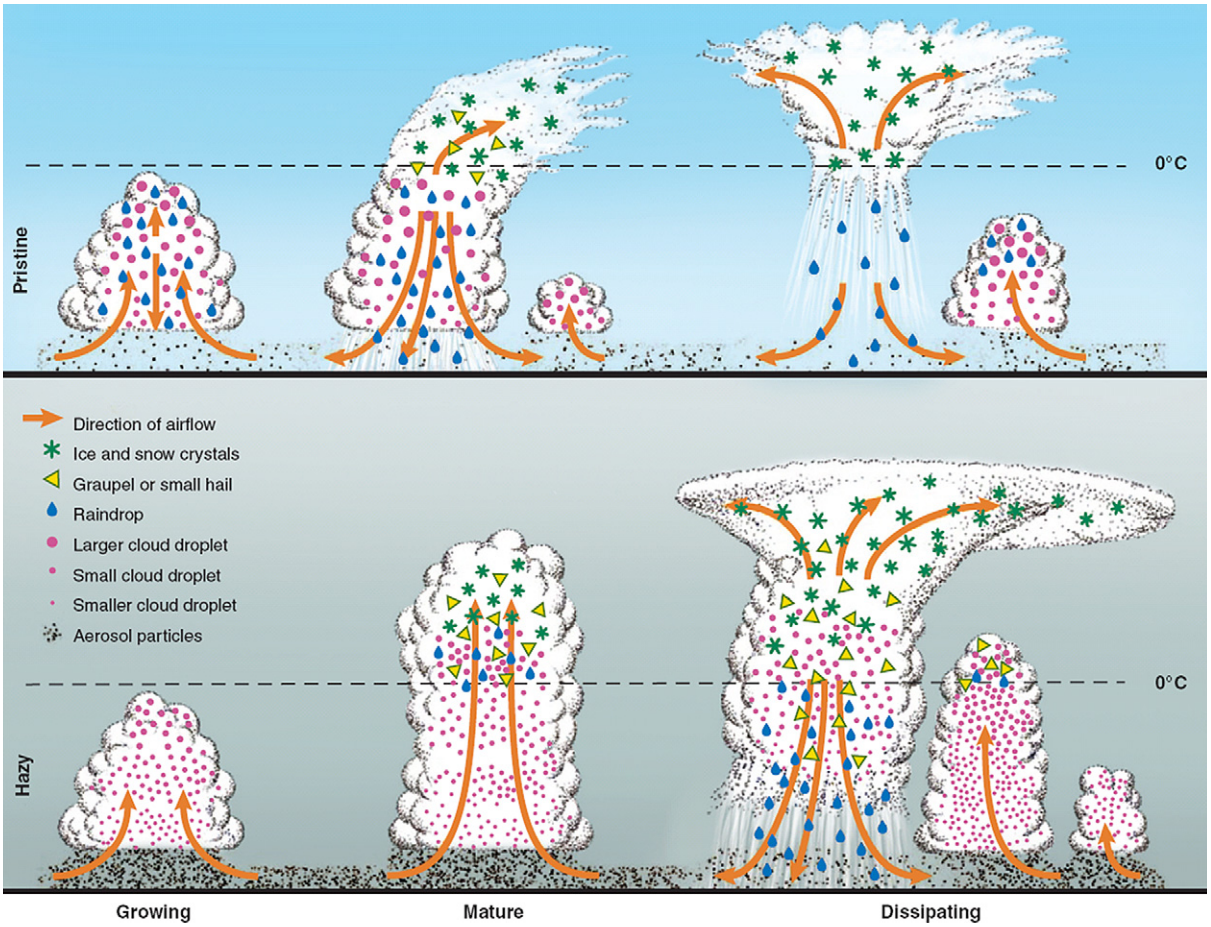

Figure 10 Evolution of deep convective clouds developing in the pristine (top) and polluted (bottom) atmosphere. Cloud droplets coalesce into raindrops that rain out from the pristine clouds. The smaller drops in the polluted air do not precipitate before reaching the supercooled levels, where they freeze onto ice precipitation that falls and melts at lower levels. The additional release of latent heat of freezing aloft and reabsorbed heat at lower levels by the melting ice implies greater upward heat transport for the same amount of surface precipitation in the more polluted atmosphere. This means consumption of more instability for the same amount of rainfall. The inevitable result is invigoration of the convective clouds and additional rainfall, despite the slower conversion of cloud droplets to raindrops. Reproduced from Rosenfeld, D., U. Lohmann, G. B. Raga, C. D. O'Dowd, M. Kulmala, s. Fuzzi, A. Reissel, and M. Andreae, 2008: Flood or drought: How do aerosols affect precipitation? *Science*, **321** (5894), 1309–1313.

Bornstein and LeRoy (1990) argued that the building barrier effect caused storms to bifurcate around New York City. Stallins and Bentley (2006) observed peaks in flash density in air mass thunderstorms on the periphery of the urban core, and the highest flash densities were associated with the urban core. Ntelekos et al. (2007) argued that the Baltimore–Washington, DC, corridor influenced the movement of storms and associated outflow boundary. Shear instability (i.e., turbulence related to differential wind velocity in the vertical) and diurnal heating can also force horizontal convective rolls in urban areas (Miao and Chen 2008). Niyogi et al. (2011) argued that storms were commonly altered by the urban landscape of Indianapolis, Indiana. Such structural changes included splitting, enhancement, and downwind mergers. Further research must shed light on whether a building, thermodynamic boundary layer, or combined barrier effects lead to such dynamical responses. It is even interesting to speculate on how the urban environment affects severe weather (e.g., tornadoes). Do such barrier effects explain the lack of tornado strikes in central business districts or is simply a function of scale? One might also posit whether the thermodynamic and moisture environments of a city can affect inflow at convective scales in severe environments (Jeff Basara, 2010, personal communication).

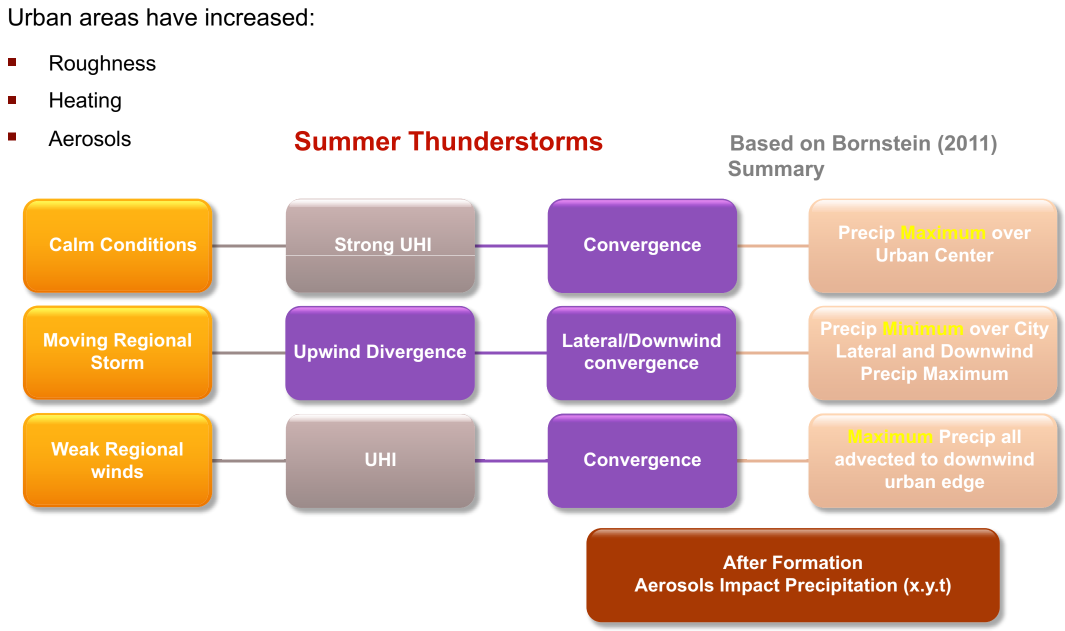
Bornstein (2011, personal communication, with modifications by S. Grimmond and M. Shepherd) attempted to provide a framework for understanding urban thunderstorm effects (Figure 11). This conceptual schematic is based on several years of research and captures some of our understanding. However, this schematic will evolve as our understanding improves.

5.07.7 Broader Context

An array of related studies continues to emerge related to urban rainfall processes. HYPERLINKvan den Heever and Cotton (2007) important study noted that urban-induced wind convergence determined storm initiation in their simulations, but aerosols influenced the amount of cloud water and ice present in the clouds. Also, aerosols were important determinants of the updraft and downdraft intensities, their life span, and surface precipitation totals. Shepherd et al. (2001) investigated rainfall efficiency in sea-breeze thunderstorms and is a nice analog to the van Den Heever and Cotton study's discussion of integrated moisture convergence (initiating the storms) and mid-level moisture (affecting the rainfall efficiency). Such synergistic modeling/observational studies that capture aerosol and urban landscape sensitivities are critically needed. Bell et al. (2008) have presented evidence of a weekly precipitation cycle over the southeastern United States that may be linked to an anthropogenic aerosol cycle. However, other studies refuted the notion of a weekly cycle (i.e., DeLisi et al. 2001; Schultz et al. 2007; Lacke et al. 2009).

Several mitigating factors constrain the expression of aerosol, thermodynamic, and surface roughness mechanisms. Such factors include topography, aerosol concentrations, or seasonality. Studies must continue to detangle these influences from any attribution studies on the URE (Shepherd et al. 2010a). Other key mitigating factors are the shape, the form, and the size of cities. METROMEX suggested that large urban areas are more likely to be associated with the URE. Yet, there is very little research (observational or modeling) on threshold sizes for cities, optimal city shapes, and the role of morphology in relation to urban rainfall anomalies.

In summary, urban environments are clear examples of how the human system can modify the natural system in terms of weather and climate. The more this complex system is understood, the better the system and optimize interactions in the coupled system can be predicted. More importantly, the ability to anticipate and manage an array of natural and societal vulnerabilities can also be improved.



Urban areas have increased:
Roughness
Heating
Aerosols
Summer Thunderstorms
Based on Bornstein (2011) Summary
Calm Conditions
Strong UHI
Convergence
Precip Maximum over Urban Center
Moving Regional Storm
Upwind Divergence
Lateral/Downwind convergence
Precip Minimum over City Lateral and Downwind Precip Maximum
Weak Regional winds
UHI
Convergence
Maximum Precip all advected to downwind urban edge
After Formation Aerosols Impact Precipitation (x.y.t)

Figure 11 Summary of urban effects on thunderstorms (courtesy of B. Bornstein).
